Form or figure is the *quality resulting in a body from the arrangement of its quantitative parts*. There is no real difference between the concepts of 'form' and 'figure,' except that the term 'figure' is used of the shape of a *geometrical* quantity, while the term 'form' is used of the shape of a natural body in its *physical* quantity as it exists in nature. In geometry, for instance, we speak of the 'figure' of a circle, of a triangle, of a square, of a cube, of a rhombus. But when speaking of actually existing bodies, we say that the 'form' of an orange is spherical, that of a pyramid is triangular, that of a shaft is cylindrical, etc. 'Form' as a

quality is altogether different from 'form' as the determining substantial principle which unites with matter in a composite substance; 'form' as a quality is here taken in the sense of 'shape' and is but an accidental modification of a bodily substance. It is well to remember, however, that in ordinary language the terms 'form' and 'figure' are sometimes used synonymously, as when people say that 'so-and-so' has a beautiful figure.'

Some *physical forms* are given by *nature* itself. The atomic structure of chemical elements possess a definite form. Many inorganic substances arrange themselves into crystals of sharply defined configurations. All plants, from bacteria to the giant sequoias, assume a form characteristic of their genus and species. The roots, stems, branches, flowers, and fruits follow a distinct pattern, notwithstanding the almost infinite number of variations found among the individuals of a species. This is also true of animals. Though unlike each other in many minor points, the individuals of a class can always be recognized by the distinctive forms of their bodies; they all conform to type. There are, of course, sports in nature which deviate from this type, but even they have a permanent form in which the general pattern can be recognized.

Other physical forms are *artificial*, the result of man's ingenuity and art or of nature's forceful activity. Man can mold and arrange the objects found as crude materials into a multitude of forms. Stones, woods, and metals are shaped to suit his manifold needs and to give expression to his aesthetic tastes. He erects buildings, constructs machines, carves statues, paints pictures, fashions clothes, landscapes

gardens, builds highways, prints books. Nature by means of wind and weather and earthquakes, raises the mountains towering to the skies, levels the plains, digs the valleys, places the rivers and oceans in their beds, directs the seasons, and in general gives shape to the world. The individual objects in none of these instances would assume these forms of their own accord and in virtue of their intrinsic nature; they do so because of the interplay of natural forces impressed upon them from without.

Whatever the individual form, whether the result of the intrinsic nature of the being itself or imposed upon it by an outside agency, the object must have within itself the *quality* which enables it to *obtain and retain* a definite form. Without such a quality things would flow from one amorphous condition of change into another, indistinct and indistinguishable as to form. The very fact that all things are built up ultimately of protons and electrons arranged into an atomic structure and a system, shows that the quality of form is inherent even in the smallest particles of material substance.

CHARACTERISTICS OF QUALITY

Qualities have *characteristics* which, though not properties in the strict sense of the term as something which emanates necessarily from the essence, are more or less *general*.

Qualities have contraries. Contraries are realities which are extremes under the same genus and cannot co-exist in the same individual. 'Being' and 'non-being,' 'life' and 'death,' and similar pairs of concepts, are not contrary, but

contradictory, and there is no common genus for such pairs, because the one member is the utter negation of the other and contains no positive reality which could be placed under the positive reality of a genus; hence, such pairs are not contrary. Qualities can be contrary, because both extremes are positive realities under a common genus. 'White' and 'black,' for instance, are the two extremes under the genus of 'color'; color is thus a quality which admits of contraries. 'Justice' and 'injustice,' though seemingly contradictory, are really contraries, considering them as *habits* affecting the will; 'moral habit' is the genus for both. So, too, 'health' and 'disease,' 'science' and 'ignorance,' considered as *states of being*, are contrary qualities. *Not all* qualities, however, have contraries. There are, for instance, no contraries to operative powers or faculties; one either possesses an intellect and will, or one does not. Neither are there contraries to form or figure; there is nothing contrary to the square or circular or triangular shape in an individual, because a 'triangle' is simply a 'triangle' and can be nothing else.

Qualities are susceptible of degrees. Many qualities can be present in varying degrees of intensity or reality. Some people have a greater capacity for knowledge than others, just as some people acquire more knowledge than others. Virtues and vices can be intensified by habits. Some habits are more deeply rooted in an individual than others, and the particular habits are increased or diminished in an individual in the course of time. Dispositions and indispositions may be present in greater or lesser degrees; thus, the feeling of well-being may be more marked at one

time than another, and neuralgia has many degrees of painfulness. Some operative powers increase and decrease in efficiency, as we observe in eyesight, hearing, locomotion, and so on. On the other hand, form and figure admit of no variations. Nothing can be more a square or less a square; a 'square' has an absolutely specified shape, and any deviation from it would make the object cease to be a 'square.'

Qualities are the foundation for similarity and dissimilarity. When things are one in substance, they are identical; when they are one in quantity, they are equal; but when they are one in quality, they are similar. In order that things can be said to be 'similar,' it is necessary that the *same kind* of quality be present in them. Two roses are similar, when both are white or red or yellow. Two patients are similar, when both have the same kind of illness. Human beings in general are similar, because their bodily form is alike. Saints are similar, because they possess virtue in a heroic degree. Since only those things are said to be (accidentally) similar which are characterized by the same kind of qualities, quality is the foundation or basis of the relation of similarity and dissimilarity; and since this is peculiar to quality, it is a *property* of quality.

MATERIALISM AND QUALITIES

Qualities have always been the bugbear of *materialistic* scientists and philosophers. In their view, the universe of bodies consists ultimately of atoms (or protons, electrons, etc.) which are indivisible and unchangeable. Elements and

bodies originate through a mere arrangement and configuration of these ultimate particles; substantial change is an illusion and abstraction. Whatever happens is the result of *mechanical motion* and gives rise to nothing more than a shift of *local relations* of a *quantitative* character among masses, molecules, atoms, and electrons and protons. These ultimate material particles are homogeneous in nature; that is to say, they are absolutely alike in essence, so that they differ only in size and shape. Hence, everything in the universe can be explained by means of quantitative structure and spatial motion, and our knowledge of things is complete when we can express them in a mathematical formula of quantitative measurement. There is no place for 'qualities' in such a materialistic and mechanistic conception of the universe; *matter in motion* is the sum-total of all objects and events. Thus, what common people and philosophers term 'quality' is reducible to 'quantity.'

The opposition of materialists to 'hidden qualities' is based on the same grounds as their opposition to 'hidden substance': our knowledge is solely a knowledge of sense-perception, and the sense *cannot perceive qualities*; hence, qualities are unknowable and as such can have no claim to existence.

When materialistic scientists advance the claim that matter and motion or energy are sufficient to explain the events of nature, they overlook the fact entirely that the *mental life of man* is also an event in the existing universe. Man is just as much a part of nature as is the atom, the proton, and the electron; and man's mind is just as much a

reality as is his body. Hence, the mental processes of man's mind must be accounted for and explained in a manner satisfactory to the demands of reason. These mental processes, however, can never be adequately explained on the mere basis of matter and the mechanical, spatial relations of motion. The energies and motions of matter, as materialists view them, are inorganic, while the mind and its processes are decidedly more than that.

Take, for example, *sense-perception*, the experience of which plays such an all-important part in the theory of materialism. All that we know of sense-perception we know through consciousness; and all we know of the world outside us we know through sense-perception: hence, all that we know about the world and ourselves rests on the ultimate testimony of our consciousness. Now, consciousness tells us that sense-perception is more than mere matter and motion. Certainly, motion accompanies all processes of sense-perception (although we are not directly conscious of this), and this motion is quantitative and can be measured. But there is much more than this to perception. *We perceive things*, not processes, with our senses. This perception itself, *precisely as 'perception,'* is something totally different from the inorganic movements of dead particles of matter: it is a *cognitive* process, a process of knowing, and that cannot be explained by the mechanical dance of the molecules, atoms, electrons, and protons which make up the material structure of the sense-organs. These 'perceptions' are as real as the particles of matter and the sub-atomic movements of these particles. These 'perceptions,' however, are something over and above the

mechanical movements of such particles: they are real *affections* in man's mental life, distinct from matter and mechanical motion, and as such are qualities. Furthermore, since these 'perceptions' cannot be explained by matter and mechanical motion, nor by the material energies present in inorganic nature, they must proceed from some *other principle* present in the mind itself. Hence, sense-perception demands a principle or power or faculty of its own, distinct from the common mechanical energies of inorganic nature, for each kind of sense has a different kind of 'perception.' But these powers or faculties we name *qualities*. Consequently, qualities exist.

Similarly, our consciousness testifies to the fact that we *think* and *will*. It would take an enormous stretch of the imagination to reduce 'thinking' and 'willing' to some form of mechanical, inorganic motion. No one can seriously assert that the formation of ideas, judgments, and inferences are motions due to cohesion, adhesion, electricity, gravitational attraction, or to any other form of energy known in the world of physics or chemistry. Nor can anyone honestly claim that love and hatred, desire and aversion, joy and sorrow, are merely forms of attraction and repulsion in a physical and chemical sense. But if not, then they, too, must emanate from principles distinct from the ordinary energies of inorganic matter present in nature. We call the principle of thinking the 'intellect' and the principle of willing the 'will.' *Intellect* and *will*, therefore, are powers or faculties; and such powers or faculties we style *qualities*. Consequently, qualities exist.

The same line of argument applies to every kind of *vital activity* found in *plant* or *animal* or *man*, in so far as they are distinctive of these classes or species. There are, of course, activities and motions present in them which are mechanical, physical, and chemical; and they can be measured according to quantitative standards. But in every organism there is a *residue of activity* which cannot be explained on the basis of matter and motion. Reason, therefore, demands that these vital activities proceed from vital powers or *faculties*. And since all faculties are qualities, qualities exist.

As a matter of fact, the materialistic scientists themselves admit unwittingly that qualities exist. They speak constantly of *energy* in nature. Most of them insist that phenomena like cohesion and adhesion, attraction and repulsion, light and heat, etc., are the results of various forms of energy, though many incline to the theory that all phenomena are the results of one fundamental energy, namely, electromagnetic energy. But *energy in some form* is accepted, together with *matter*. Even such a crass materialist as Büchner admitted the existence of *Kraft und Stoff* (Force and Matter). But what is 'force' or 'energy,' if not the 'power or capacity to do work' in some form or other? Energy is not the work itself that is done, but the *power or capacity* to do work. 'Power,' however, is what we call a *quality*. To refuse to accept the existence of 'quality,' while they accept the existence of 'energy,' is an inconsistency which ill becomes them; because 'energy' is not a datum of sense-perception at all, but something which reason demands as an adequate explanation of existing

phenomena as we perceive them. Here again, as in the case of 'substance,' materialistic scientists admit the *thing*, though they will not admit the *name*. Moleschott, for example, accepted 'chemical affinity' as a fact of nature. F. A. Lange accused him with fine irony of inconsistency, in the following words: "Here we find Moleschott deep in scholasticism; his 'relationship' [between oxygen and potassium] is the prettiest *qualitas occulta* [hidden quality] that can be wished for. It sits in the oxygen like a man with hands. If potassium comes anywhere near, it is laid hold of; if none comes, at least the hands are there, and the wish to get hold of potassium."⁵ And so the arguments of materialists simmer down to a quarrel of words.

In a discussion of this kind it is sufficient to prove that *one* quality exists; it settles the argument. Once the existence of a quality of any kind is proved and accepted, there should be no trouble in accepting the various kinds of qualities. While any serviceable division is satisfactory, Aristotle's division has the advantage of compactness and completeness. We have therefore followed him in his enumeration of qualities: habit and disposition; natural capacity and incapacity; affective qualities and affections; form and figure. Something might have been said of the 'relative' character of some of the qualities, but relation' is a separate category which will be treated in the next chapter.

SUMMARY OF CHAPTER XIX

Quality is the first of the categorical accidents with which ontology is concerned; the category of 'quantity' will be treated in cosmology.

1. *The Concept of Quality.* 'Quality' admits of no strict philosophical definition, because 'accident' is not a univocal term and thus cannot be used as a proximate genus. 'Quality' can be described as an absolute accident, completing and determining a substance in its *being* and in its *operation*. Aristotle enumerates four types: habit and disposition; natural capacity and incapacity; affective quality and affection; form and figure.

2. *Habit and Disposition.* A *habit* is a comparatively permanent quality disposing a thing well or ill in its being. A *disposition* is a relatively transient quality which disposes a thing well or ill. An *operative* habit disposes a thing well or ill in its operation. Strictly speaking, only a free faculty is capable of habit; such is the will of man. Indirectly, under the influence of the will, other faculties can be said to acquire habits. Some habits are natural, others acquired; there are also supernatural habits.

3. *Natural Capacity and Incapacity.* A natural *capacity* is the proximate accidental principle of operation, toward which (operation) it is specifically directed. All beings — inorganic, vegetative, sentient, and rational — possess natural capacities. An incapacity is an existing *faculty* in a weakened or unfit condition.

4. *Affective Qualities and Affections.* An affective quality is a relatively permanent quality which produces, or results from, some accidental sensible alteration. If such a quality is more or less ephemeral in character, it is an *affection*. The 'sensible qualities' of color, sound, etc., and also their 'perception,' belong to this class. The soul also has affective qualities and affections. Chief among the affective qualities of the soul are the *temperaments*. A temperament may be choleric, phlegmatic, sanguine, or melancholic.

5. *Form and Figure.* Form or figure is a quality resulting in a body from the arrangement of its quantitative parts. Geometrical shapes are called 'figures'; physical shapes are called 'forms.' Some physical forms are natural, others artificial.

6. *Characteristics of Quality.* Qualities have contraries. Qualities are susceptible of degrees. Qualities are the foundation for the relation of similarity and dissimilarity.

7. *Materialism and Qualities.* Generally speaking, materialists try to explain all things in the universe as matter in motion.

They are opposed to 'hidden qualities,' because qualities cannot be perceived by the senses. However, sense-perception is not the only source of knowledge; *reason* is a valid source, otherwise scientific *induction* is invalid.

Matter, force, energy, atoms, protons, and electrons, accepted by materialists, cannot be perceived by the *senses*; their existence is guaranteed by *reason*.

The *perception* of things, as cognition, demands a mental principle or faculty. *Thinking* and willing are not mechanical; they demand the faculties of intellect and will.

The same is true of all vital functions. *Energy*, as a *capacity* for work, is a quality. Hence, qualities exist.

Chapter 20

RELATION

‘RELATION’ AND THE ‘RELATIVE’ ARE CONCEPTS WHICH PLAY A very important part in modern philosophy. The *relative* stands in opposition to the *absolute*. One can safely state that in the past century and a half philosophers have written more about these two concepts than about any other two concepts within the whole range of philosophy. Modern philosophy has been, and still is, chiefly concerned with the problem of human knowledge, and in this problem the ‘relative’ and ‘absolute’ are the key ideas. These concepts are the foundation for entire systems of thought. This alone shows the importance of the category of ‘relation.’

THE CONCEPT OF RELATION

What constitutes a ‘relation’? Three factors or elements are necessary and suffice to constitute a ‘relation’: the subject, the term, and the foundation. The *subject* of the relation is the thing *that* is related to another. The *term* of the relation is the thing to which the subject is related. The foundation of the relation is the basis, the ground, the *reason why* the

subject is related to the term. The 'subject' and the 'term' are also styled the *extremes*, because the 'foundation' is the connecting link or bond which unites the subject and term together and places them 'in relation' to each other.

From this it should be plain that one thing alone, taken for itself, can never form a relation; relation must exist *between two or more things* taken in reference to each other. The essence of 'relation,' considered formally as such, consists in the '*esse ad*,' the '*being-toward*' of one thing to another; it is the bearing, the reference, the attitude, the ordination of one to another due to some foundation which is a common bond between them. The *foundation* is the necessary *condition* for a relation, but it is not the 'relation' itself. The foundation is present in both the subject and the term, and it is because of this foundation that the subject and the term are connected, giving each a 'respect toward' the other, so that they are thereby 'related' or 'in relation.' Two white horses, for example, are similar to each other in their white color; their whiteness is not the relation of their similarity; but it is the reason or foundation of their relation of similarity; as such, then, they stand to each other in a 'relation of similarity' because of the white color present in both. The 'relation,' therefore, *results from* the presence of a common foundation in a subject and term and is considered to be, at least conceptually, distinct from the foundation, the subject, and the term.

No strict definition of 'relation' can be given. The only concept which could be used as its proximate genus in such a definition would be 'accident.' But 'accident,' as was

pointed out before, is not used univocally of its inferior members; it can be applied to the various categories only in an analogous sense. Using a descriptive definition, we define *relation* as the *bearing* (reference, respect, attitude, ordination) *of one thing to something else*.

KINDS OF RELATION

All relations can be grouped into two main classes: *logical* and *real*.

Logical Relation. A logical relation is defined as a relation *made solely by the mind and placed by the mind between entities*. Such entities may exist outside the mind, or may be concepts, judgments, and inferences existing in the mind itself. The foundation for such a relation is an *ens rationis*, a logical entity. There is no real foundation in the extra-mental things themselves for making such a relation; the relation, therefore, is strictly a product of the mind's thinking. Thus, we systematize our ideas and in this manner bring them into relation with one another, when we study a certain branch of knowledge: such relations are logical. Between every subject and predicate in a sentence there exists a certain relation of comprehension and extension: this is also a logical relation. So, too, there is a definite relation of sequence between the premises and conclusion of an inference; and also between a number of inferences in an extended argumentation: such relations, however, are logical, because they exist solely in the mind and its operations.

In a similar manner, we often place relations between objects *outside the mind*, although these relations have no reason or foundation in the properties of the things themselves. The relation between the little black marks of print on this page and the ideas which they represent and convey to the reader, is purely logical, because these black hooks and dots have no significance except in so far as the mind selects and designates them to have a meaning. A scepter represents royal dignity; a palm, victory; a red light, danger; a flag, a country: but the relation between these things is purely of the mind's own making and has no foundation in the things themselves.

Real Relation. A real relation is defined as a relation which exists *between things, independent of the mind and its thinking*. The subject and the term are real entities in nature; the foundation of the relation is present in them *objectively* and is not merely conceived by the mind as being there. There is thus a connection or bond between real things, due to something present in them, independent of all thought; and this connection or bond would exist, even if there were no mind adverting to it. Such a relation exists, for instance, between parent and offspring, between plant and flower, between two pups of the same litter, between two trees of equal height, between two houses of the same architectural style, etc.

A real relation may be either essential (transcendental) or accidental (categorical, predicamental). An *essential* (or *transcendental*) relation is one in which the very *essence* of one thing has a relation or bearing toward something. This relation will, therefore, always be present as soon and as

long as this essence is present; the essence cannot exist without this relation. Thus the relation between every being and an intellect and will, making this being 'true' and 'good,' is essential and transcendental, because it is an essential and transcendental attribute of all being to be true and good. Every creature owes its entire essence and existence to the Creator, and the relation of the creature to the Creator is thus an essential one. The relation between body and soul in man is an essential relation, because both are ordained toward each other to form a composite substance, and this ordination lies in their very essence. A similar condition obtains between every incomplete substantial part and the substantial whole of which it is the part.

An *accidental* (or *categorical*, or *predicamental*) relation is one based upon an *accident* as its foundation. The accident which serves as the foundation for the relation is something superadded to the essence and its absence would not destroy the essence itself. Two children have blond and curly hair; in this respect they stand to each other in the relation of similarity. Two men are six feet tall; they are related to each other through the equality of the quantitative measurements. Obviously, 'blond and curly hair' and the equal 'height of six feet' are accidental modifications of these persons and do not belong to their essence.

From another standpoint relations are divided into *mutual* and *non-mutual*.

A relation is *non-mutual*, if its foundation is *real or logical in one of the extremes only*. A case in point would be

the relation of knowledge between the knowing subject and the known object. The foundation or basis of the relation is the transition from a state of non-knowledge to a state of knowledge with regard to some definite object; this transition involves a real change. It is obvious, however, that only one extreme undergoes this transition and change, namely, the knowing subject which acquires the knowledge. The relation of knowledge is real only on the part of the knower; on the part of the thing it is only logical.

On the other hand, a relation is *mutual*, if its foundation is *real or logical in both extremes*. If two horses are white, the foundation of the relation of their similarity, namely, 'white color,' is present in both horses. In children of the same parents the relation of origin is present in each, and this relation is mutual. When two poles have a length of ten feet, the foundation of their equality in length, namely, their quantity, is found in each pole, because each one is ten feet long, independent of the other; the relation, therefore, is mutual.

A mutual relation is said to be one of the same *denomination* or *symmetrical*, when the foundation in both extremes is of the *same nature* and *degree*. The whiteness of the horses, the common origin of children in the same family, the equal length of the poles, as mentioned in the preceding paragraph, are of the same denomination, because the foundation is of the same nature and degree in each.

A mutual relation is said to be of *mixed denomination of asymmetrical*, when the foundation present in both extremes is of a *different nature or degree*. Father and child

are related; but the father is the cause, while the child is the effect. This means a difference of foundation in both and consequently also a difference in relation of the one to the other, because filiation implies a state of dependence of the child with respect to its father, while paternity implies a state of independence of the father with respect to his child. Many relations are of this kind; for example, that between husband and wife, master and servant, physician and patient, lawyer and client, judge and criminal, teacher and pupil, superior and subject, king and people, and so on.

The examples given above for mutual relations pertain to all relations which are mutually present in both extremes, whether of the same or of a mixed denomination. Mutual relations, however, may also be purely *logical*. Such mutual logical relations would rest upon a foundation which is conceptual or logical in *both extremes*. Thus, all relations existing between concepts, judgments, and inferences rest upon foundations which have no existence except in the mental order, because the concepts, judgments, and inferences themselves are logical entities and as such have no existence outside the mind. Such would be the relation between subject and predicate in a sentence, all relations of grammatical construction, etc. Formal logic, or the science of correct thinking, is practically a treatise on mutual logical relations.

THE FOUNDATION OF RELATION

The foundation of relation, as was stated before, is the basis, the ground, the *reason why* one thing is related to

another. Almost anything can be taken as the point of comparison, so as to establish a relation between things. Every category contains such foundations.

Substance contains the foundation for *specific identity and diversity*. Two flasks of water, two elm trees, two sparrows, two men, etc. (the two members of each pair being compared together), are identical in species; and each pair, compared with another pair in this series, is different in species. We thus have the relation of specific identity existing among all the individuals of a certain species, and the relation of specific diversity among the individuals of different species.

Quantity contains the foundation for the relation of *equality and inequality*. Things that have the same weight, size, volume, shape, or dimensions are equal to each other on account of their quantity, while things which differ from each other in these respects are unequal. Two globes of the same diameter have the relation of equality; a quart and a gallon of wine have the relation of inequality.

Quality contains the foundation of *similarity and dissimilarity*. For example, we speak of two painters as being similar or dissimilar in their technique; of two philosophers as being similar or dissimilar in their opinions; of two dogs as being similar or dissimilar in their behavior.

Action and passion (reaction) contain the foundation of the relation of *cause and effect*. We observe this relation extensively in mechanical, physical, and chemical agencies. Salt is the effect of the combination of sodium and chlorine, and as such it is in relation to these two chemicals. Iron is attracted to a magnet; the two are thus related. Electricity

produces light and heat; these are, therefore, related to electricity as effects to their cause.

Time contains the foundation for *priority, simultaneity, and posteriority* in successive duration. The murder of Julius Caesar is in the relation of priority to the death of Napoleon; the murder of Julius Caesar, however, is in the relation of posteriority to the death of Aristotle.

Place contains the foundation of the relation of *distance, nearness, and relative position*. The moon is nearer to the earth than to the sun; between the moon and the earth, therefore, there is the relation of comparative nearness. The positions of north, east, south, and west, or right and left, or before and behind, or up and down, or inside and outside, etc., give rise to relations among objects.

Posture and *habitus* contain the foundation of the relation of *similarity* and *dissimilarity* between things, but in a different manner than the qualities. To be prone, or to be erect, makes objects either similar or dissimilar; thus, there is a relation of dissimilarity between one man lying down and another man standing. So, too, to be clothed or not clothed, shod or not shod, etc., makes two persons either similar or dissimilar.

From this it will be seen that every category contains items which may be the foundation for various sorts of relations between things.

SOME AXIOMS CONCERNING RELATION

Correlatives are simultaneous in nature. By this we mean that related things, precisely and *formally* as in relation to

each other, must exist at the same time and the one cannot exist before the other. Thus, 'mother' and 'child' are correlatives. Obviously, the mother as a 'woman' or 'human being' exists before her child. But as a 'mother' she must have a 'child,' and she cannot be a 'mother' before she has a 'child'; at the very moment when her child begins to exist she is a 'mother,' and not a moment sooner nor a moment later.

Correlative's are simultaneous in knowledge. This means that the knowledge of one extreme as 'relative' always involves the knowledge of the other extreme as 'correlative.' And in truth, it is impossible to know what 'parent' is without also knowing what 'offspring' is. If we know that the Washington Monument is smaller than the Empire State Building, we must have a knowledge of the size of each.

Correlative's connote each other. This means that the intelligibility of the one extreme is dependent on the intelligibility of the other; they can be understood only in reference to each other. This follows from the foregoing principle. The concept of 'offspring' involves the concept of 'parent,' and *vice versa*. That two figures are similar to each other in their triangularity implies that the understanding of the 'triangular shape' of the one involves the understanding of the 'triangular shape' of the other; otherwise it would be impossible to know that they are similar. Hence, no relative term, strictly as 'relative,' can be defined without bringing the correlative term into the definition, because they cannot be understood except in reference to each other.

EXISTENCE OF REAL RELATIONS

The philosophy of relations gives rise to a very serious problem. Are relations merely the product of our minds and their relating activity, so that things are 'conceived' as related to each other simply because the mind has a natural tendency to arrange and classify all things in conceptual groups? Or, are relations also present in nature, among the things existing in the universe, so that these things are related to each other, even though no mind be thinking of them? In short, are relations merely conceptual and *logical*, or are they actual and *real*?

Many philosophers deny that relations are real and maintain that all relations are *purely mental and logical* in character. Modern phenomenologists and idealists are especially persistent in their view that the entire conception of order in the universe is *projected* into it by the mind. *Kant*, for example, maintains that our knowledge is the result of applying certain innate mental forms to the chaotic manifold of sense-intuitions, thereby bringing order and definite relations into them. The monistic idealists, like *Fichte*, *Hegel*, etc., contend that our *knowledge is constitutive of reality* as we experience it. If this were true, all relations would, of course, be purely mental and logical, because all knowledge would then be completely mind-made: in this view, the mind would not acquire its knowledge by conforming itself to the things, but things acquire their reality by being conformed to the mind. It is not the purpose of ontology to prove the existence of a physical world which is independent of the mind; this is a

fact which epistemology must vindicate.¹ Here we accept the reality of the physical world and maintain that *some relations are real* and independent of the mind.

In order that a relation may be real and not merely logical, the following *conditions* must be fulfilled: the subject of the relation must be real; the term must be real; the foundation in the subject must be real; the foundation must be really distinct from the term. In other words, there must be a real, individual subject, a real, individual term, and a real foundation existing in both extremes.

First of all, the *natural sciences* teem with demonstrations of real relations in nature. The scientific classification of plants and animals is based upon *structural similarity*. The only reason why science can arrange plants and animals in a hierarchical order of kingdoms, phyla, classes, orders, families, genera, species, and individuals, is because each individual is similar to others in certain well-marked properties and peculiarities. These properties and peculiarities are real in each individual, independent of the mind which recognizes them. Certainly, no one would seriously claim that science first made these structures similar. Hence, if there is structural resemblance among plants and animals in nature, real relations exist in nature.

Again, there is *dependence* in nature. Plants are dependent on various things in nature for their existence and substance: air, soil, light, warmth, moisture. Animals need plants for food, and man needs both animals and plants. In the case of bi-sexual forms of plants and animals, the sexes are dependent upon each other for the propagation of their kind. This dependence is without

question a real fact of nature, and is not a product of our thinking. But 'dependence' of one upon another is a reference, an ordination, of one thing to another. And since this is the relation of a real dependence of one real being upon another real being, real relations exist in nature.

Nations with their governing and governed classes, international commerce, diplomatic service, wars, peace contracts, industrial and agricultural difficulties, cultural, social and religious contacts, etc. — these and similar things are realities in human society and in the world, independent of our thinking. They constitute real relationships among real people.

Furthermore, physics and astronomy assure us that all beings in the universe, from the electrons and protons in the atoms to the interstellar nebulae and star-galaxies, are continuously in motion and are drawn toward each other in virtue of gravitational attraction. All this implies a 'reference of one to the other' with regard to *distance, position, and relative motion*. The only way to deny the fact of their real relation would be to deny the fact of their real existence; only a confirmed subjectivist, however, would do that.

Then, too, *active production* is a universal fact of nature. Leaving the formation of chemical compounds aside, there can be no question that living beings produce living things. This is true of plants and animals, as well as of men. If so, then the relation of *offspring to parent* is a real relation. It would assuredly be ridiculous to assert that plants and animals propagated their species only after man's mind adverted to them. But if plants and animals did propagate

before the coming of man, the relation of offspring to parents was a fact in nature before man's mind was present to 'relate' them. But a relation between real beings, based upon a real foundation like generative production, is a real relation, independent of man's mind and its thinking.

Hence, if we accept the existence of a real world outside the mind, we must also accept the existence of real relations among the things of this world. No thing can exist together with other things, without some real relations being established between them.

THE ENTITY OF REAL RELATION

Every relation contains three factors: a subject, a term, and a foundation. The 'relation,' considered strictly as such, is not the 'subject' itself nor the 'term' itself, because the relation is the *bond* which connects and links the extremes together, so that there is a reference or ordination of each to the other. Nor is the relation, considered strictly as such, the 'foundation.' The foundation is the basis, the ground, the reason for the relation. The foundation is always some reality, essential or accidental, which is either a 'being-in-itself' or a 'being-in-another'; the relation, however, is formally a '*being-toward*' something. Hence, there is no question that there is a distinction between the concept of the 'relation' and the concept of the 'foundation.'

Is the *distinction* between the 'relation' and the 'foundation' real or only *virtual*? If we maintain a real distinction between them, we must consider the 'relation' to be an *accidental entity or mode* superadded to the entity of

the foundation in the extremes. This would mean, for example, that, besides the quality of 'whiteness' which makes two horses similar, there would be a distinct entity or mode of 'similarity' added (as a relation) to the 'whiteness' in each horse. If we maintain only a *virtual* distinction between them, the 'relation' would be no *new entity or mode* added to the extremes besides the foundation itself. This would mean, in the example given, that the relation of 'similarity' between two white horses would be in reality identical with the quality of 'whiteness' present in each horse. We maintain that only a *virtual distinction* exists between the relation and the foundation. In order to prove this, we appeal to the following principles and facts.

If the 'relation' were really distinct from the foundation, it would follow that the 'relation' would be a real entity or mode which would be *acquired* when a relation is established, and *lost* when a relation is discontinued. However, to acquire or lose a real entity or mode involves a *real change*, and that could be accomplished only by some positive *action producing* the change. Hence, if it can be shown that relations are acquired or lost without a real change occurring in one or both of the extremes, it will be shown thereby that the relation does not consist in a real entity or mode. But this can be shown.

To take an example. In South Africa there exists a pole fifty feet in height. A man in Alaska erects a pole which is also fifty feet in height. The poles are now related to each other through the 'relation of equality.' If this relation be a real entity or mode, the pole in South Africa acquires a new entity or mode which it did not possess before; it has

undergone a real change thereby. What possible agency can have introduced this change and given it a new entity or mode? It seems incredible that the mere erection of a pole in Alaska should be able to effect a real change in a pole in South Africa. Since no conceivable real change took place in the latter, we must conclude that a 'relation' does not add any real entity or mode to the extremes which would be distinct from the entity of their foundation.

Again, *substance and accident are correlatives*; they are 'related.' The inhesion of the accident in the substance is the foundation connecting them. If this relation were a real entity or mode, distinct from the entity of the extremes and the foundation, this entity or mode of the 'relation' would also be an *accident*, an accidental reality; and as such it, too, would 'inhere' in the substance. Thereby a second 'relation' would be established. This second relation, being an accident also, establishes a third 'relation' between itself and the supporting substance. This third must bring a fourth 'relation' into existence, for the same reason. The fourth must produce a fifth, and so on, into infinity. Thus, an *infinite number* of entities or modes would be introduced into a substance, simply because we maintain that the relation is a real entity or mode, distinct from the entity of the extremes and their foundation. An infinite number being impossible, the 'relation' cannot be a real entity or mode.

Finally, an *immense aggregation* of real entities or modes would exist in each individual being, if we maintain that a 'relation' is an entity or mode distinct from the extremes and the foundation. Not only between every

individual being as a whole and every other individual being in the universe, but also between every single atom of every being and every other atom in the universe, there exist relations of specific identity or diversity, of similarity or dissimilarity, of equality or inequality, of distance, time, position, action, etc. Thus, an incalculable multiplicity of real entities or modes would be introduced into each being, shifting and changing from moment to moment. By merely crooking my finger, I would actually produce a *physical change* (change of relation, due to distance, position, etc.), throughout the universe. This, however, seems incredible. It is an unnecessary *multiplication of beings*, and beings should not be multiplied without sufficient reason. Such a view involves a *power of activity* in each and every being far beyond the exigencies of their nature, because this active power of change would reach to every being within the utmost bounds of the world. Hence, we must conclude that relations are not real entities or modes.

If, however, a relation is *not really distinct* from the extremes and the foundation which constitute the factors of a relation, then the reality of a 'relation' must be somehow *identified with* the extremes and the foundation. The question, therefore, arises: With which factor is the relation identified, with the subject, the term, or the foundation? Or, is it identified with all three factors? The 'relation' is *not identifiable* with the *subject* and *term*. The subject and term (extremes) are not the 'relation,' because they are the things which *become related* through the connecting bond of the relation. And how do they 'become related'? What is the connecting bond which makes them 'related' to each

other? It is the 'foundation' which places them 'in relation' to each other. It follows that *the entity of the relation is one with the entity of the foundation*. In reality, then, the 'relation' and the 'foundation' are identical so far as their entity is concerned, and there is no real distinction between them.

Nevertheless, there is a *virtual distinction* between 'relation' and 'foundation.' The foundation is conceived as that reality in things 'because of which' a relation exists between the things; hence, in concept there is a distinction between the foundation and the relation, because the relation 'follows out of' the foundation. An example will make this clearer. Two globes are 'similar' to each other because both are 'white.' The first globe is 'white,' and the second globe is 'white.' This 'whiteness' exists in each, independent of the other; and it is a real accidental entity present in each. There are, therefore, two 'whitenesses' in existence, and these *two* 'whitenesses' (one in each globe) are the foundation for the one *relation of similarity*. Since the relation is one, while the foundation is twofold, and since the foundation (whiteness) exists in the globe, while the relation (similarity, due to the whiteness) exists *between* the white globes, it is obvious that a virtual distinction exists between the 'foundation' and the 'relation.' This distinction between the two concepts being grounded in the objects themselves, due to the twofold foundation, we come to the final conclusion that the distinction between the reality of the 'foundation' and the reality of the 'relation' is a *virtual distinction* with a foundation in the thing (*distinctio virtualis cum fundamento in re*): they are identical in

reality, but distinct in concept, and the ground for the distinction is not purely mental, but is present in the things themselves.

THE ABSOLUTE AND THE RELATIVE

It has become almost a commonplace in modern philosophy to say that all being and all knowledge is only 'relative.' The reason for this spurious axiom lies in the fact that anything, in order to be known, must enter into a relation with the mind and as such must be 'relative to mind.' It is, of course, true that nothing can be known unless it enter into a relation with the mind, because 'knowledge' in its very concept and essence implies such a relation. But this only means that a thing, *when known*, has a relation to the mind and that the knowledge of the thing is dependent on this relation; it does not mean that the thing, *as existing*, is dependent on the mind and its knowledge-relation, so that the *existence* of the thing would be dependent on our knowing it. A thing must exist before it can become known; as such, it must be 'absolute' before it can become 'relative' to our mind.

All creatural beings are, in a true sense, 'relative.' They are *dependent on God* as their First Cause for their being and existence; and 'dependence' is a form of relation. This relation of the creatures to the Creator is essential to them, and they can never free themselves from it. Taken in this meaning, only God is 'absolute,' because He alone is without dependence on any other being.

Creatural beings are also related in many ways *among themselves*. All, compared to each other, are similar or dissimilar, equal or unequal, acting or acted upon, specifically identical or diverse.

While relations, therefore, exist among all beings, it would be an erroneous view to hold that there is nothing 'absolute' in things. *Things are both 'absolute' and 'relative.'* That all things can be said to be 'relative,' we have just seen. That they are also 'absolute' in some form, is also true.

A thing is said to be *relative*, when it is taken *in reference to something else*; it is *absolute*, when it is *taken in itself and on its own account*. A relation always implies the three factors of subject, term, and foundation; and the relation, formally considered as 'relation,' is conceived as something 'existing between' the subject and the term due to their common foundation. The 'subject' and 'term' must be distinct in entity. No being is said to be 'related' to its own self; it is always in reference to *something else*. Consequently, both the subject and the term must be 'something in itself and on its own account' before either can have a reference to the other. If they had no being or existence of their own, they could never have a reference to anything. But to have a being and existence of its own means to be 'something in itself and on its own account,' and that means to be *absolute*. Things, therefore, cannot be 'relative' unless they are first 'absolute.' From this it is clear that creatural beings in the universe are both absolute and relative.

But is this not a *contradiction in terms*? Certainly, if it were stated that something were 'absolute' and also 'relative' from the same standpoint and in the same respect, a contradiction would be involved in the statement. A thing, however, can very well be 'relative' from one standpoint and 'absolute' from another; there is no contradiction then. And that is precisely the case in the question under consideration. Considered in themselves and for themselves all things have a being and existence of their own, independent of the being and existence of other things; viewed from this standpoint they are *absolute*. Compared, however, with other things, they are either similar or dissimilar, equal or unequal, etc.; viewed from this standpoint, they are in relation to these others with which they are compared, and as such they are *relative*. As a matter of fact, they can be 'relative' *to others* only because they are 'absolute' *in themselves*. Hence, there is no contradiction in stating that things are both 'absolute' and 'relative,' because the standpoint is different for each designation.

It should now be easy to solve the problem: Can the mind of man *know the 'absolute' or only the 'relative'*? Many modern philosophers claim it can know nothing but the 'relative.' *Sir William Hamilton*, for example, accepts "the great axiom that all human knowledge, consequently that all human philosophy, is only of the relative and phenomenal. In this proposition, the term *relative* is opposed to the term *absolute*; and, therefore, in saying that we know only the relative, I virtually assert that we know nothing absolute — nothing existing absolutely; that is, in

itself and for itself, and without relation to us and our faculties.”² Herbert Spencer speaks in a similar vein: “Thinking being relationing, no thought can ever express more than relations.”³ Such views are false. To know that a relation exists, we must know that certain things are related. If we do not know these things as they exist in themselves and for themselves, we cannot know the ‘foundation’ in them which makes the one to be the ‘subject’ and the other the ‘term’ of the relation. But this we can and do know.

When we perceive two houses built according to the same plan, we perceive three things: the first house, as it is in itself and for itself; the second house, as it is in itself and for itself; and the identity of plan in each, on account of which they are said to be related as ‘similar.’ If we did not first perceive each house and its plan separately, as *an entity distinct in itself and for itself*, we could never recognize the ‘similarity’ which exists between them. But to perceive each house in this manner is to perceive each one as it exists *absolutely*. Only then do we perceive their similarity and with it the ‘relation of similarity’ which exists between them, so that they can be said to be ‘related to each other.’ Hence, the knowledge of things as ‘relative’ presupposes the knowledge of them as ‘absolute’: we must always know the terms of a relation before we know the relation itself. Consequently, *the knowledge of the absolute is prior to the knowledge of the relative*.

We may summarize our doctrine of relation in a few sentences: Not all relations are logical in character; some relations are real in nature; the entity of the ‘relation’ is

really identical with the entity of the 'foundation' in the extremes, with a virtual distinction between them; a knowledge of the 'absolute' is necessary before a knowledge of the 'relative' is possible.

SUMMARY OF CHAPTER XX

Much of modern philosophy is based on the concept and category of relation.

1. *The Concept of Relation.* Three factors are involved in relation: subject, term, and foundation. Relation is the bearing (reference, respect, attitude, ordination) of one thing to something else.

2. *Kinds of Relation.* All relations are either logical or real. A *logical* relation is one made solely by the mind and placed by the mind between entities. A *real* relation is one which exists between things, independent of the mind and its thinking.

A *real* relation is either essential (transcendental) or accidental (categorical, or predicamental). It is *essential*, when the very essence of one thing has a relation toward something. It is *accidental*, when the relation is based upon an accident as its foundation.

Relations are also mutual or non-mutual. It is *non-mutual*, if its foundation is real or logical in one of the extremes only. It is *mutual*, if its foundation is real or logical in both extremes. A mutual relation is of the same denomination, when the foundation in both extremes is of the same nature and degree; otherwise, it is of mixed denomination.

3. *The Foundation of Relation.* The foundation is the *reason why* one thing is related to another. Almost anything can be taken as the point of comparison. Every category contains foundations for relations.

4. *Axioms Concerning Relation.* Correlatives are simultaneous in nature. Correlatives are simultaneous in knowledge. Correlatives connote each other.

5. *Existence of Real Relations.* Not all relations are purely logical; some are *real in nature*. The systematization of science (e.g., botany and zoology) is based on structural similarity among things as they exist. There is dependence of one thing on another in nature. Nations and human beings in general have real relationships. The production of living beings through generation is a fact of nature. Our consciousness testifies to the fact that the things themselves impose the knowledge of their relations upon us.

6. *The Entity of Real Relation.* A 'relation' is not an *entity* or *mode* superadded to the entity of the foundation in the extremes. No such entity or mode is required in order to explain the presence of a relation; the existence of the *extremes* and their *foundation* automatically makes the extremes related. If the relation were a new entity or mode, things would be changed with a real alteration without any action. An infinite number of relations would exist in each individual. Things would actively influence every being throughout the universe. This is incredible. Hence, there is only a *virtual* distinction between the 'relation' and the 'foundation.'

7. *Absolute and Relative.* All things are related in some way; in this sense it is true to say that all things are 'relative.' In order, however, that things can be 'relative' to *others*, they must be 'absolute' in *themselves*; that is, they must be something in themselves and for themselves,

before they can have a reference to other things. We cannot know that things are 'similar,' 'equal,' etc., to each other, unless we know them first as they are in themselves. Hence, the knowledge of the absolute is prior to the knowledge of the relative.

Chapter 21

ACTION, REACTION: CAUSE, EFFECT

IN PASSING FROM THE CATEGORIES OF QUALITY AND RELATION to those of *action* and *reaction* (*passion*), we approach one of the profoundest problems of metaphysics, the problem of *change* and *causality*. This problem, perhaps more than any other, turned the minds of the early Greek thinkers toward a discussion of the origin and constitution of the physical world. That was the beginning of Greek philosophy.

It would be an erroneous view of the world to think of it as an unchanging, static reality *in facto esse*, i.e., in a condition of completed development. And it would be just as erroneous to consider it as an altogether non-permanent, dynamic reality continually *in fieri*, i.e., in a process of ceaseless change and becoming. The fact is, changes occur in things relatively permanent by means of action and reaction.

CONCEPT OF CAUSE AND EFFECT

Whenever a change takes place, it proceeds from an *operative potency*, from an active power or faculty. The exercise, or operation, of an operative potency (active

potentiality, power, or faculty), is called *action*; and the being which possesses this operative potency, is called the *agent*. By means of the action of its operative potency the agent produces a change in itself or in another as the recipient of the action. The *reception* of the action on the part of the recipient is called *reaction* (*passion*); the recipient is called the *reagent* (*patient*). Every change, therefore, presupposes an active potentiality in the agent and a passive potentiality in the patient. The active potentiality of the agent acts and produces a change, while the passive potentiality of the patient is acted on and undergoes the change. By means of its action the agent actualizes the passive potentiality of the patient, and therein consists the 'change.' The change, therefore, as it *proceeds* from the agent, is the *action*; this same change, as it is *received* by the patient, is the *reaction* (*passion*).

In all *transient* actions, the agent and patient are individual beings, really distinct from each other. The wind which agitates the water of a lake is really distinct from the agitated water; the burning wood which cooks the food is really distinct from the food itself; the jigsaw which carves the wood is really distinct from the carved wood. But in *immanent* actions the agent and patient are entitatively the same individual, and there is on that account only a virtual distinction between the agent and patient. Nutrition, for instance, is an immanent action in an organic being, perfecting this organic being itself. Thinking and willing are immanent actions which actualize the faculties of intellect and will in the rational being itself, so that this rational being is both agent and patient. The action, since it is the

exercise of an operative potency (power, or faculty), is *really* distinct from this operative *potency* and from the *agent*. The power, or faculty, remains in the agent, while the action comes and goes. Active thinking, for example, proceeds from the faculty of the intellect in repeated actions, but the intellect itself, whether active or inactive, remains in the soul as a permanent operative potency.

What has been said here of action and reaction refers to *creatural* beings. In an *analogical* sense action is also attributed to *God*. God, however, being infinitely perfect and totally substantial, has no operative faculties and actions in the meaning just given, otherwise there would be accidental potentiality and accidental actuality in His being. In our limited understanding of the divine perfections, we have no intuitive knowledge of God's being. The best we can do is to attribute the perfection of action, as we observe it in creatures, to God, after we have removed the imperfection of potentiality from it, and then deny all limitation and composition of this perfection. In God essence and action are absolutely identical and infinitely perfect, while in creatures agent and action are really distinct and very limited in perfection. When, therefore, we attribute 'action' to God, we must always bear in mind that the term is used only in an analogical sense.

AS FOUND IN CREATORIAL BEINGS, ACTION ALWAYS IMPLIES A change, and change implies *causality*. The 'agent' is the 'cause'; the 'action' of the agent producing the change is the 'causality'; the 'change' produced in the patient as

reaction is the 'effect.' But this is the meaning of 'cause' in the restricted sense of an efficient cause. The term 'cause' has a much wider significance than this.

In the traditional view a *cause* is defined as *that which in any way whatever exerts a positive influence in the production of a thing*. Three factors enter into the concept of 'production': that which produces, or the *cause*; that which is produced, or the *effect*; and the positive influence of the cause in the production of the effect, or the *causality*. Everything depends upon this positive influence in the production, in order that a thing may be called a 'cause.'

For this influence to be really 'causal,' it must *affect the being of a thing in its production*. There is no causality unless there is a 'production,' and 'production' means the bringing of a substantial or accidental thing from a state of potentiality (actual non-existence) to a state of actuality (actual existence). Such a production evidently affects the 'being' or entity of a thing in some productive manner.

This *productive influence* on the being of a thing is the most important factor in causality. *Mere external sequence* or connection on the part of two things is not sufficient to bring them into the relation of cause and effect. The fact, for example, that one train follows another along the tracks, establishes no causal relation between them, because the connection between them is purely extrinsic.

For the same reason a purely *logical influence* of one thing on another is insufficient to constitute causality. The Principle of Contradiction, for instance, exerts a tremendous influence upon all our thinking. Its influence, however, is 'logical,' not 'causal'; this principle does *not*

produce our thinking, nor does it confer anything toward the production of the *entity* of our thought. It is the intellect which actually produces our thought and as such is its 'cause.' The influence of the cause may be either corporeal (seed, for example, producing a plant) or spiritual (the intellect, for example, producing thought); but in order that such an influence partake of the nature of causality it must be *productive of being* in some manner. This will become clearer, when we compare the concepts of 'principle' and 'cause.'

PRINCIPLE AND CAUSE

In general, a *principle* is defined as *that from which something proceeds in any manner whatever*. In order that something be a 'principle,' it is required: that the principle be *prior* to that which proceeds from it; and that this priority be grounded in the things themselves because of some *special connection* existing between them.

There are two main kinds of priority: the priority of *reason*, and the priority of *reality*. These are also called *logical* and *real* priority. 'Logical' priority is attributed to a thing which, although it precedes another neither in time nor in nature, has within itself the ground on account of which our mind conceives it as preceding the other. Thus, according to our human way of thinking, the 'essence' of God is prior to His 'attributes' of intelligence, omnipotence, etc., because the essence is the ultimate ground of being in anything. Hence, we consider God's essence to be the 'principle' of His attributes.

‘Real’ priority, or the priority of reality, can be threefold: one of *time*, or of *nature*, or of *origin*. A thing is said to have priority of *time*, when it has existence before that which proceeds from it. A mother, as a human being, exists before her child. A thing has priority of *nature* with regard to another when this other presupposes the natural entity of the first for its own entity, even if the existence of both be simultaneous. Thus, a substance is prior in nature to its accidents, even though it have no priority of time with respect to its accidents; the ground for this priority of nature lies in the fact that the ‘substance’ is the necessary support for the entity of the accidents inhering in it. A thing has priority of origin, when it precedes another in such a manner, that there is a procession of the one from the other without any strict and real dependence.

Thus, in the Blessed Trinity, as theologians explain, the Logos proceeds from the Father, and the Holy Spirit proceeds from the Father and the Son (Logos). Due to this procession, the Father is prior in origin to the Son, and both the Father and the Son are prior in origin to the Holy Spirit. Since all three divine Persons possess the same nature, there is no priority of nature among them; and since this procession is eternal, there can be no priority of time.¹

It should now be clear that we must distinguish between a ‘principle’ and a ‘cause.’ *Every cause is a principle, but not every principle is a cause.* A cause is always a ‘principle,’ because it is a thing from which another (the effect) proceeds. A ‘cause,’ however, is that which exerts a

positive influence in the *production* of a thing; and that does not apply to every 'principle,' because there are some principles (for example, logical principles) which do not produce anything. The concept of 'principle' is thus seen to be wider than that of 'cause.' Hence, we may also define *cause as a principle of production*, and this definition is only verbally different from the one given above.

For something to be a real cause or principle of production, *three conditions* must be fulfilled. First of all, the cause must be a real and positive *entity*; a negation or privation is never given the name of a 'cause.' A negation or privation is the absence of entity and as such is actually nothing; but what is actually nothing cannot exert a positive influence in the production of anything. Then, the cause must really contribute some *influence* in the production of the effect. This also follows from the fact that a cause is conceived as a principle of production. The effect is the result of a production which originates in the cause. If the cause exerted no positive influence, this production could never originate, and the effect would never come into being. Hence, a mere precedence in time or place is not sufficient to constitute a cause. Finally, the effect must be *really distinct* from the producing cause. The cause 'produces' the effect; it must, therefore, produce something distinct from itself. The cause must evidently exist, in order to produce something; if the effect were not distinct from the producing cause, the cause would of necessity *produce itself* although it has existence already. That, however, is impossible: if it 'exists,' so as to be able to produce an effect, it can no longer produce itself in order that it 'obtain

existence' as the effect of its productive act. Hence, the effect and the producing principle must be diverse.

THE MAIN KINDS OF CAUSES

Two main theories have attempted to give an adequate explanation of the facts of change in the universe: *mechanism* and *naturalism*. The theory of materialistic mechanism, as was pointed out on a former occasion (Chapter 19), maintains that the ultimate constituent particles of matter are homogeneous in character, actuated by purely mechanical forces which produce only local movement. According to this mechanistic explanation of change and production, the only causes existing in nature are efficient causes. The theory of *naturalism*, as advocated by Aristotle and the scholastics, maintains that the beings possess a 'nature,' in virtue of which they are specifically distinct substances with specific properties and activities. Each nature existing in this physical universe is a compound, consisting of a 'material' and a 'formal' element as its constituent causes. By means of their powers and actions they change other beings, either in an accidental or substantial manner, thereby acting as 'efficient' causes in changing these beings. Such changes, however, do not occur in an entirely haphazard manner. On the contrary, the hierarchical arrangement of natural beings according to a definite plan and the constant functioning of natural forces according to physical laws, seems to show clearly that all things in the universe follow certain tendencies and ends; hence, 'final' causes also operate in the changes which take

place in the world. According to the theory of naturalism, therefore, four distinct types of causes account for the 'how' and 'why' of all beings: *material*, *formal*, *efficient*, and *final*.

Aristotle, the first to attempt a thorough analysis of cause in all its phases, gives the following explanation of the number and character of the four causes just mentioned. "We aim at understanding, and since we never reckon that we understand a thing till we can give an account of its 'how and why,' it is clear that we must look into the 'how and why' of things coming into existence and passing out of it, or more generally into the essential constituents of physical change, in order to trace back any object of our study to the principles so ascertained.

"Well, then (1) the existence of *material* for the generating process to start from (whether specifically or generically considered) is one of the essential factors we are looking for. Such is the bronze for the statue, or the silver for the phial. [Material causes.] Then, naturally, (2) the thing in question cannot be there unless the material has actually received the *form* or characteristics of the type, conformity to which brings it within the definition of the thing we say it is, whether specifically or generically. Thus the interval between two notes is not an octave unless the notes are in the ratio of 2 to 1; nor do they stand at a musical interval at all unless they conform to one or other of the recognized ratios. [Formal causes.] Then again, (3) there must be something to initiate the process of the change or its cessation when the

process is completed, such as the act of a voluntary agent (of the smith, for instance, [making a bronze statue, as mentioned in Bk. II, Ch. II]), or the father who begets a child; or more generally the prime, conscious or unconscious, *agent* that produces the effect and starts the material on its way to the product, changing it from what it was to what it is to be. [Efficient causes.] And lastly, (4) there is the *end* or purpose, for the sake of which the process is initiated, as when a man takes exercise for the sake of his health. 'Why does he take exercise?' we ask. And the answer 'Because he thinks it good for his health' satisfies us. [Final causes.] Then there are all the intermediary agents, which are set in motion by the prime agent and make for the goal, as means to the goal. Such are the reduction of superfluous flesh and purgation, or drugs and surgical instruments, as means to health. For both actions and tools may be means, or '*media*,' through which the efficient cause reaches the end aimed at. This is a rough classification of the causal determinants of things."²

If we seek to determine why there are just *four causes*, no more and no less, we can find the *necessity* for this number in the following reasons. A cause is something on which the production of a being depends. This caused being can be considered in a twofold way. If we consider it absolutely, the cause of the being, making it to be actually what it is, is its *form* (*formal* cause). If we consider it as a potential being becoming an actual being, two factors are

necessary to reduce it from potency to act. There must be the material factor, or matter, which is reduced from potency to act (*material* cause); and there must be the agent which, by means of its action, reduces it from potency to act (*efficient* cause). Since, however, an agent can act only according to the tendency of its own determined nature, and a tendency implies a definite direction or end, this end also determines the production of the caused being (*final* cause).³

To put the subject in a different way: There are four questions which can be asked of a thing, in order to explain the 'how and why' of its being. If we ask '*By what* is it made?' the answer is 'By the efficient cause.' If we ask '*Out of what* is it made?' the answer is 'Out of its material, its material cause.' If we ask '*Through what* is it made?' the answer is 'Through its form, its formal cause.' And if we ask '*On account of what* is it made?' the answer is 'On account of the end or purpose which induced the agent to act.' By answering these questions with respect to a thing we obtain the various determining factors which explain the production of the thing and make it to be what it is. Since these answers explain the whole thing in its being and in its production, we have all the causes which account for its 'how and why' and these causes are just four in number.

In order that these four determinant factors really deserve to be called 'causes' it is necessary that they actually be *principles of production* for the being of the thing said to be the 'effect.' That they actually are such, will now have to be shown. 'Material' and 'formal' causes belong properly to cosmology and psychology; hence, they

will be treated in brief fashion, mainly for the purpose of obtaining an understanding of these terms.

THE MATERIAL CAUSE

It is through the process of change that we arrive at the concept of material cause. A thing is said to 'change' when it passes from being one sort of thing into being a different sort of thing. There are two kinds of change: *accidental and substantial*. Both are common occurrences. When water changes from a solid to a liquid or to steam, it still retains its nature as 'water'; this is an accidental change. When a block of marble is carved into the figure of George Washington, it undergoes a change, since it is now something different from what it was before; but this change of shape does not affect the nature of marble as 'marble,' and so the change is accidental. Many changes, however, alter the very nature and substance of things. A plant, for instance, will absorb various kinds of elements from the soil and change them into living tissue, so that these elements unite into organic compounds and perform functions more or less contrary to their natural tendencies; such a change is substantial. Again, animals will take inorganic elements and the organic compounds of plants, assimilate them through a digestive process, change them into animal tissue, and utilize them in the cognitional process of sense-perception in a manner far superior to their own natural propensities; such a change in the elements, when compared to their original nature, is truly substantial, because they are now integral parts of a higher

substance, having changed from non- living to living beings. Reversely, too, when living tissues break down in the organism, or when plants and animals die and decay, a substantial change of an opposite character takes place, because living compounds thereby become non-living.

Whether a change be accidental or substantial, there is always a *substratum* or *base* present which persists throughout the process of change, which passes *from potency to act*. This substratum is something indifferent, potential, receptive, passive, determinable, actualizable; it is that which is changed, determined, actualized. This substratum is that out of which something becomes or is made; and this is called the matter or the material cause.

In an *accidental* change this matter or material cause is the *complete substance* acquiring some accidental 'act' or 'form.' A block of marble, for example, has the potentiality of receiving the shape of a statue, a column, an urn, a fountain, a bench, a table, etc. It is the 'matter' or 'material' out of which any of these things can be fashioned.

In a *substantial* change there must also be a material factor or matter. Whenever there is a change of one substance into another, as when non-living substance is changed into living substance, a *substratum* passes through the whole process. This substratum is the *primal matter*. It is present in the inorganic elements; it is also present, when the elements are changed into the living substance of the plant; and it remains present, when the plant substance is digested by the animal and becomes animal substance. Hence, primal matter has the capacity or potentiality of being changed from one kind of substance into another,

depending on the kind of agent which acts upon it. Hence, primal matter is a true cause, because it is that *out of which* something is made.

THE FORMAL CAUSE

The formal cause is the correlative of the material cause: matter and form always go together, because they are related to each other as *act* and *potency*. Matter is indifferent; the form is definite. Matter is passive; the form is active. Matter is receptive; the form is that which is received. Matter is potentiality; the form is act. Matter is determinable; the form determines it. Matter is actualizable; the form actualizes it. Matter is that 'out of which' something is made; the form is that 'through which' a thing is made to be what it is.

Since changes may be accidental or substantial, the form acquired in the change will be either an *accidental* or a *substantial* form. An accidental form is some reality determining the complete substance, such as quality or quantity, or a modification of quality or quantity. When a drop of water freezes, the crystalline structure is an accidental form or act communicated to the water. When a lump of clay is modeled into different shapes, these shapes are accidental forms or acts determining the indifferent clay. When the mind thinks, these thoughts are accidental forms or acts perfecting the perfectible mind. When a child grows to full stature, this growth is an accidental form or act affecting its quantity. In all these cases, the substance as such remains intact throughout the change.

But in substantial changes, the *nature* or *substance* is transformed into a new nature or substance through the access of a new substantial form. The substantial form unites with primal matter to constitute *a specific nature*. It is that essential and constitutive principle which makes a man to be specifically a 'man,' a lion to be specifically a 'lion,' a dog to be specifically a 'dog,' a rose to be specifically a 'rose,' and so forth. Primal matter is common to all these beings; and if matter were the only essential principle present in them, there would be no specific difference between them. What makes them specifically different among themselves, is the specifically different substantial form present in them, determining the indifferent primal matter to be just this kind of being and no other. When the substantial form changes, the species changes. The substantial form is united intrinsically to primal matter and takes away from the latter all its indifference and indeterminateness.

An example will perhaps make this relation between matter and form clearer. Take, for instance, a piece of beef. The matter in it is indifferent to becoming any particular kind of new being. It may be eaten by a lion, or a tiger, or a jackal, or a dog, or a cat, or a man. Whatever animal eats this meat, breaks down the beef tissue into minute particles, and by a process of assimilation turns it into flesh of its own kind. The inherent indifference of the primal matter is thereby removed, and this matter receives specifically new characteristics, due to the action of the new being into which it passes. There must, then, be a specifically different formative principle or 'form' in each of

these types of animal. Such a substantial form must exist in the lion, making it to be just a 'lion' and nothing else; and that also applies to the tiger, the jackal, the dog, the cat, and man. That the beef ceases to be 'beef' and becomes lion flesh, or tiger flesh, etc., must be due to a substantial form, peculiar to the species, found in each individual of the type or class; and this formative principle then actualizes and determines the indifferent primal matter by depriving the meat of its beef form and substituting its own as the actualizing agency.

This substantial form is truly a *cause*, because it assists intrinsically in the production of a being by means of a positive influence. Together with primal matter it is a *constitutive principle* of the composite substance, determining it essentially in the line of substantiality and specific perfection: it actualizes the potentiality of primal matter and makes it to be a definite substance of a definite species. All corporeal beings are thus essentially composed of substantial matter and substantial form. This theory of the composition of bodies is the *hylomorphic* theory (ύλη matter, and μορφή, form) of Aristotle and the scholastics.

THE EFFICIENT CAUSE

The efficient cause is that by which something is produced. A being of one kind is changed into a being of another kind by means of action. The agent or efficient cause acts upon another being and effects a change in it, thereby producing a new act or form. When scientists speak of 'causes' in

physical phenomena, they refer to these efficient causes and their action.

In our discussion so far, we have spoken of 'production' in the sense of change of one kind of being into another kind of being, as it occurs mainly in corporeal beings; in such changes a pre-existing matter or material cause is presupposed. It would be erroneous, however, to restrict the action of efficient causes to such a production. Creation is also 'production,' and it demands an efficient cause to bring a nonexistent being into existence; in this case, however, no pre-existing matter is present out of which, as out of a passive potentiality, the new thing originates.

Of all the causes which assist in the production of an effect by means of a positive influence, the efficient cause is most readily recognized as being a true cause. Its influence is unmistakable. When a mason builds a brick wall, his action certainly influences its making, and he is the efficient cause of the wall. When the expansive power of steam drives a locomotive along the rails, its action produces the motion and it is the efficient cause of this motion. When hydrogen and oxygen are brought together under proper conditions, their action upon each other results in the formation of water; they are the efficient cause of the new compound. And so with other agencies in nature. Since a real production takes place, the agent responsible for it is an efficient cause.

THE FINAL CAUSE

The final cause is that *for the sake of which* an efficient cause acts. It is the end, the purpose, the intention, which dominates and determines the action of the efficient cause in its production of something. This purpose *induces* the agent to act and determines the *kind* and the *manner* of action, so that the end or purpose may be achieved. The concept of a final cause or 'purpose in views involves the concept of a plan of action and the use of the proper means to attain the end.

That man does things for a definite purpose or end, is a matter of daily occurrence. When a carpenter intends to make a table, he selects the wood, cuts it into proper lengths, each piece having a definite shape and thickness, nails them together according to a plan determined by the particular kind of table he desires, and in this manner achieves the purpose he had in mind before he began to work. That the end or purpose positively influences the action of the efficient cause, is clear; the end or purpose is thus seen to be a *true cause*. It is called the *final* cause or end-cause.

Of the four causes here mentioned, two are intrinsic and two are extrinsic. The *two intrinsic causes* are the material and the formal cause. Matter and form are constitutive principles of things, entering into the very composition of their being. This is especially the case with corporeal beings or physical bodies where substantial matter and substantial form are the essential part-substances which combine to constitute the corporeal compound. Since the nature and constitution of physical bodies is the special object of investigation in cosmology, matter and form will be

discussed at length in that department of philosophy; nothing further will be said of them in ontology.

The two *extrinsic causes* are the efficient cause and the final cause. They do not enter into the composition of the being of things, but act upon them 'from without.' These two types of causes are found in material as well as in immaterial beings; their nature is, therefore, more of a metaphysical character. Hence, we must now treat of efficient and final causality a little more in detail.

SUMMARY OF CHAPTER XXI

Changes occur in things relatively permanent by means of *action* and *reaction* (*passion*). Action and reaction are the basis of causality.

1. *Concept of Cause and Effect.* Change proceeds from an operative potency. The exercise of this potency is 'action.' The reception of this action in the subject is 'reaction' or 'passion.' By means of this action the agent actualizes the passive potentiality of the patient, and therein consists the 'change.'

A *cause* is defined as *that which in any way whatever exerts a positive influence in the production of a thing.* Causality must affect the being of a thing in its production.

2. *Principle and Cause.* A principle is that *from which something proceeds* in any manner whatever. The two main kinds of priority involved in a principle are the priority of reason (logical priority) and the priority of reality (real priority). Every cause is a principle, but not every principle is a cause. The cause is a principle, because something (the effect) proceeds from it. But not every principle is a cause, because some principles (e.g., logical principles) do not produce anything. Hence, a cause can also be defined as a 'principle of production.'

For something to be a cause or principle of production, *three conditions* must be fulfilled: the cause must be a real and positive entity; it must influence the production in a real manner; the effect must be really distinct from the producing cause.

3. *The Main Kinds of Causes.* There are four main kinds of causes: *material*, *formal*, *efficient*, and *final*. They explain the 'how and why' of a being. The material cause is that 'out of which' something is made. The formal cause is that 'through which' something is made. The efficient cause is that 'by which' something is made. The final cause is that 'on account of which' something is made.

4. *The Material Cause.* Changes are either accidental or substantial. There is always a *substratum* or *base* present which persists throughout the change. This is the matter or material cause *out of which* the thing is made.

5. *The Formal Cause.* Matter is that 'out of which' something is made, while the 'form' or 'formal cause' is that *through which* a thing is made to be what it is. In accidental changes this form is some accidental reality determining the complete substance. In substantial changes this form unites with primal matter to constitute a *specific nature*. When the substantial form changes, the species changes. Matter and form are the constitutive principles of a composite substance, determining it essentially in the line of substantiality and specific perfection. This theory is called the hylomorphic theory.

6. *The Efficient Cause.* It is that *by which* something is produced. A being of one kind is changed into a being of another kind by means of the action of the agent or efficient cause. Creation is also a kind of efficient causality. When scientists speak of natural causes, they mean efficient causes.

7. *The Final Cause.* It is that *for the sake of which* an efficient cause acts. It is the end, the purpose, the intention,

which dominates and determines the action of the efficient cause in its production of something.

The material and formal causes are *intrinsic* to the things produced, while the efficient and final causes are *extrinsic*.

Chapter 22

EFFICIENT CAUSALITY

SCIENTISTS AND PHILOSOPHERS OFTEN SPEAK A DIFFERENT language, when they discuss questions referring to 'causes and 'causality.' The scientist, as a scientist, is not supposed to be a philosopher and metaphysician. He is not interested in the ultimate explanation of things, but in those which are relatively proximate in character. In his proper field of research the term 'cause' has a different meaning for him than it has for the metaphysician who seeks to penetrate into the deeper reasons of things. What the scientist calls 'physical causes' are but the necessitating and indispensable *conditions* or *antecedents* of physical events, not the 'producing agencies' which exert a positive influence in bringing things from non-existence to existence through a process of productive change or through creation. Thus, John Stuart Mill says: "The causes with which I concern myself are not *efficient*, but *physical* causes. They are causes in that sense alone, in which one physical fact is said to be the cause of another. Of the efficient causes of phenomena, or whether any such causes exist at all, I am not called upon to give an opinion."¹

As long as the scientist restricts himself to this negative attitude, the philosopher need not quarrel with him. But sometimes the scientist surreptitiously turns metaphysician and denies the validity of the concept of efficient causality as proposed by the philosopher. According to him the 'physical causes,' in the sense just indicated, are the *only* true causes; 'efficient causes' simply do not exist in nature. It thus becomes imperative to vindicate the validity of the concept of 'efficient causes' and 'efficient causality' in a philosophic sense.

CAUSE, CONDITION, OCCASION

In order to arrive at a better understanding of the problem, it will be necessary to recall what has been said about the nature of an efficient cause, as outlined in the foregoing chapter, and compare it with 'condition' and 'occasion.' These concepts are closely allied.

A condition is something required in order that an efficient cause can act, but it does not contribute any positive influence toward the production of the effect itself. That the filament of an electric bulb may become incandescent, it is necessary to push the button of the switch, so that the electric circuit will be closed; but the pushing of the button does not make the filament glow. Clear weather is a condition for effective artillery action; but the weather has in itself nothing to do with shooting off a cannon.

If a condition is so necessary that the efficient cause cannot produce its effect under any circumstances without

it, it is called a *conditio sine qua non*, i.e., 'a condition without which the cause does not act.' Thus, the knowledge of a good is the *conditio sine qua non* for an appetitive faculty to strive for the good. Light is the *conditio sine qua non* for the act of seeing. It is obvious, however, that the intellect itself does not 'strive' for the good, but the appetitive faculty; nor does the light 'see,' but the eyes.

Sometimes the 'condition' consists merely in the *removal of an obstacle* for the cause; the presence of the obstacle hinders the cause from acting. Thus, if a person's feet are tied, it is a necessary condition for walking that the impediment be removed. If a person is locked in a room, the door must first be unlocked before he can leave the room. The rope and the locked door are obstacles which must be removed; but that the person actually walks, that is due to the person's own efficient causality.

An *occasion* is a *circumstance or combination of circumstances which affords an opportunity for an efficient cause to act*. A crowd is an occasion for a pickpocket to ply his trade. A tavern may be the occasion for a drunkard to indulge his pet vice. Election time is the occasion for political oratory. The meeting with a friend may be the occasion of a confidential chat. The difference between an 'occasion' and a 'condition' should be fairly obvious. A condition is such that its fulfillment or presence is *required* in order that an efficient cause can act; an occasion is not a requirement for action, but its presence is something which merely gives the *opportunity* for action. Thus, the presence of a tavern gives a drunkard the opportunity to obtain the liquor needed to get intoxicated, and the tavern is for this

reason an 'occasion' for intoxication; but the possession of a quantity of liquor, sufficient to become intoxicated, is required, and this possession is, therefore, a 'condition' for intoxication.

Neither a condition nor an occasion amounts to the causality of an efficient cause. They exert an indirect influence on an agent to act, but it is the *action of the agent* which positively influences the production of something; and *efficient causality* consists precisely in this productive action of the agent. To take the example just mentioned; it is neither the presence of the tavern (occasion) nor the possession of the liquor (condition) which makes the drunkard intoxicated, but the actual drinking (action) of the man himself (agent).

KINDS OF EFFICIENT CAUSES

Efficient causes may be viewed from a variety of standpoints. This gives rise to a number of classifications.

First Cause and Second Cause. By 'First Cause' we understand one whose causality is *absolutely independent* of any other cause or being, and on which all other causality depends. This is God. God is the uncaused Cause of all things. Since He is the source of all being, He must be independent of all beings in everything He is. And since all beings owe their essence and existence to Him, their causality is ultimately dependent on Him. By 'second cause' we understand one whose causality is *dependent* on some other cause or being. Since all creatural beings are dependent in their essence and existence on God, the First

Cause, their causality is also dependent on Him. Hence, creatural beings are 'second causes.'

Physical and Moral Cause. A 'physical' cause is one which produces an effect by its own *direct action*. For example: the carpenter who makes a table, the boxer who defeats his opponent by knocking him unconscious, the boy who throws a snowball through a window, the violinist who draws his bow across the strings, the philosopher who thinks, the orator who gives a speech. A 'moral' cause is one which *inclines a free agent to act*; this may be done by an appeal, by a threat, by a promise, etc. The politician is a moral cause, when he induces an official to give him a position by paying him a sum of money. A criminal who extracts money from his victim by means of blackmail, is a moral cause. The detective who wrings a confession from a suspect by threats of the 'third degree,' is a moral cause.

Principal and Instrumental Cause. A 'principal' cause is an efficient cause which produces an effect *in virtue of its own power*. An 'instrumental' cause is an efficient cause which produces an effect *in virtue of the power of another cause*. Principal and instrumental causes are correlatives; the one implies the other. A carpenter uses a saw to cut a board; the saw is the instrumental cause, the carpenter is the principal cause. A hunter kills a deer by shooting it with his rifle; the rifle is the instrumental cause performing its action under the direction and control of the hunter. It should be noted that both causes exert their own peculiar causality. The saw cuts and the rifle shoots; but they would not act at all and not in this particular manner, were it not for the direction and control of the principal cause.

Cause per se and Cause per accidens. A cause is said to be a cause *per se*, if it has the *natural tendency* to produce a particular effect or, if it be a free agent, if it *intends freely* to produce it. It is a cause *per accidens*, if it produces an effect toward which it has *no natural tendency* and which the free will (if that be the cause in question) does *not intend*. When I take a hammer and deliberately drive a nail into a board, I am the cause *per se* that the nail enters the wood; but if I thereby hit my finger, I am the cause *per accidens* for that, because I did not intend that particular effect as the result of my attempts at carpentering.

Proximate and Remote Causes. A 'proximate' cause is one which produces its effect *directly*, in virtue of its own action, without using the action of some intermediate cause. When I walk, eat, push a cart, swing a stick, catch a ball, etc., I am the proximate cause of these effects, because they are the results of my own direct action. In melting snow, in boiling water, in making a piece of iron glow, in expanding the mercury in a thermometer, etc., heat is the proximate cause, because these phenomena are the direct result of the heat's action. A 'remote' cause is one which produces an effect through the direct action of some *intermediary cause* or causes. When my finger pulls the trigger of a rifle and explodes the charge of the cartridge, a bullet is ejected which travels through the air and kills a deer at a considerable distance; the bullet is the proximate cause of the death of the deer, while the exploding charge, the action of my hand and arm, and the deciding influence of my will, are the remote causes of the killing. Naturally, the ultimate cause in this particular chain of causes is my will.

Total and Partial Cause. A cause is said to be the 'total' cause, when the *entire* effect is produced by its action; if only a *part* of the entire effect can be attributed to a particular cause, it is a 'partial' cause. The masons, carpenters, plumbers, plasterers, etc., who assist in the construction of a building, are all part-causes of the construction. But when I lift a plank, push a table, walk a mile, dig a hole, throw a ball, etc., I am the total cause of these effects.

Univocal and Equivocal Cause. A 'univocal' cause is One which produces an effect *similar to itself in nature*. Thus, the oak produces an oak, the maple a maple, the dog a dog, the robin a robin, man a man. Living beings, therefore, which reproduce their own kind, are univocal causes in this respect, because these effects are similar to themselves in nature. An 'equivocal' cause is one which produces an effect *dissimilar to itself in nature*. When a dog, for example, gnaws a bone, the splintering of the bone is an effect dissimilar to the nature of the dog; the dog is the equivocal cause of this effect. When a robin builds a nest, the robin is an equivocal cause of the nest. A painter is the equivocal cause of his paintings, a writer, of his writings, a builder of his buildings, because the effects are different in nature from himself as their cause.

Necessary and Free Cause. A 'necessary' cause is a cause which is *determined by its nature* to produce a certain effect, provided the requisite conditions are present. If I throw a stone into the air, gravity must pull it back to the earth, because gravity is a necessary cause and is determined to a definite line of action without choice. A

'free' cause is a cause which is *not compelled to act*, even though all the requisite conditions for action are present. Thus, man is free in very many of his actions, like walking, eating, smoking, playing, etc. He can perform them or omit them, as he chooses.

After this brief enumeration and explanation of the various classes of efficient causes, as handed down to us by the traditions of philosophy, we must turn our attention to the far more important question of the existence of such efficient causes. In considering this question, we must accept the term 'efficient' cause in the meaning previously given: as something which, through its positive action, produces something.

THE EXISTENCE OF EFFICIENT CAUSES

Briefly, the status of the question is this: Is there really a *causal connection* between things? Does the being and existence of things really depend intrinsically upon other things?

Does one reality actually *produce* another reality? In a word, are there efficient causes in the universe?

Phenomenalism in its various guises denies the existence of efficient causes. It contends that we cannot possibly know anything of the reality of 'causes.' 'Cause' is an obscure metaphysical notion without any objective foundation in the things or in the events of nature. Our knowledge is restricted to sense-perception; and the senses can contact only the phenomena or appearances of things, but not their inner nature or energy. Hence, according to

phenomenalistic philosophers, the only facts accessible to our knowledge are objects in a *local* and *temporal* sequence: things are perceived as following each other; that is the total extent of our valid knowledge. We perceive *antecedents* and *consequents*, nothing more. Man arbitrarily changes this local and temporal sequence in serial happenings into an imagined 'causal connection,' in virtue of which the later phenomenon is considered to be 'produced' by the earlier.

David Hume attacks efficient causality in the following words: "When we look towards external objects, and consider the operation of causes, we are never able, in a single instance, to discover any power or necessary connection; any quality, which binds the effect to the cause, and renders the one an infallible consequent of the other. We only find, that the one does actually, in fact, follow the other. The impulse of one billiard-ball is attended with motion in the second. This is the whole that appears to the outward senses. The mind feels no sentiment or *inward* impression from this succession of objects: consequently, there is not, in any single, particular instance of cause and effect, any thing which can suggest the idea of power or necessary connection."² He then takes the case of the will commanding bodily members to act, and argues:

"The motion of our body follows upon the command of our will. Of this we are every moment conscious. But the means, by which this is effected; the energy, by which the will performs so extraordinary an operation; of this we are so far from being immediately conscious, that it must for ever escape our most diligent enquiry."³ *John Stuart Mill*

agrees with this view of Hume: “The Law of Causation, which is the main pillar of inductive science, is but the familiar truth, that invariability of succession is found by observation to obtain between every fact in nature and some other fact which has preceded it; independently of all considerations respecting the ultimate mode of production of phenomena, and of every other question regarding the nature of ‘Things in themselves.’⁴

For *Kant* and his disciples, a knowledge of efficient causes in the world is also impossible, but for a very different reason. According to the traditional view, these efficient causes would be the things-in-themselves, as they exist outside the mind in the universe. The mind, however, according to Kant, cannot know such things-in-themselves. ‘Causality’ is a *category* of the mind, and the ‘category’ is an innate, *a priori* mental form which acts as a regulative principle in arranging our judgments. But the category of causality is not derived from our experience of things and events as they actually exist in nature, and as such tells us nothing about the efficient causality of such things. The causal connection which we place between things and events is purely mind-made and has value only for the mind and its operations.

The *occasionalists*, like Malebranche and some others, accept the efficient causality of God, but *deny* it altogether of *creatures*. God is the only efficient cause in existence. If creatures seem to produce effects, this is only a mistaken notion on our part: it is God alone who acts, using the creatures as His instruments.

In opposition to these views, we contend that the concept of efficient cause is an objectively valid concept, based on the data furnished by *experience* and demanded by reason as the only true explanation of the facts. What we must prove, of course, is, that a mere 'invariable sequence of antecedents and consequents' is not sufficient to account for our concepts of 'cause and effect,' but that there exists the *actual production* of one thing or event by another thing or event.

PROOF FOR EFFICIENT CAUSALITY

In proving the existence of efficient causality among things, it will be necessary first to show that the *assumptions* which underlie the position of the opponents are unwarranted; then it will be necessary to adduce the *positive evidence* which supports the view that efficient causality actually is present in nature.

The opposition against the existence of efficient cause is based primarily on an adverse *theory of knowledge*, and not on the facts themselves. As such, the denial is made primarily on epistemological grounds. *Kant*, since he maintained that we can have no knowledge of things-in-themselves, naturally had to deny any knowledge of efficient causality as existing among these things-in-themselves. It is the purpose of epistemology to vindicate the sources of our knowledge, among them being sense-perception, consciousness, and reason. In this connection we will restrict ourselves to one consideration. If Kant's fundamental assumption were correct, we could know

nothing of the existence and activity of *other minds* beside our own, because these 'other minds' are evidently things-in-themselves. But we have a *knowledge of other minds*. This is proved conclusively by the fact of language, whether spoken or written or printed. We do not use language to converse with ourselves; conversation is essentially a dialogue between our mind and 'other minds.' Hence, we can and do acquire knowledge of things-in-themselves, as they exist in themselves, through the medium of language. Kant's fundamental assumption is, therefore, incorrect. Consequently Kant is wrong, when he asserts that we could know nothing of efficient causality if it existed among things. If we can show that efficient causality exists in *ourselves*, we prove that efficient causes exist in nature, because we ourselves are a part of nature.

Hume, Mill, and others, denied efficient causality because of their *phenomenalism*. According to their assumption, all we can perceive are the phenomena, and phenomena are revealed to us in our senses merely as events in invariable sequence. Whenever, then, we perceive phenomena as invariably succeeding each other in place and time, we are prompted by habit and the association of ideas to imagine a *causal connection* to exist between them, so that the earlier event is the 'cause' and the later event the 'effect.' This is, in their view, the origin within our mind of the concept of efficient causality.

This is a deplorable error. The fact is, we clearly distinguish between mere 'invariable sequence' and 'real causality.' We notice, for example, an invariable sequence between day and night every twenty-four hours, and we are

convinced that this sequence has been maintained throughout the ages; at any rate, we have never experienced a single exception in this sequence. We also notice, when the day is hot and humid, and a sudden, decisive drop in temperature occurs, that a rainstorm develops; this sequence, however, is by far not as invariable as the sequence between day and night. No one, however, dreams of considering day and night as being in any causal connection, as if the day 'produced' or 'caused' the night. On the other hand, we certainly are convinced of the existence of a causal connection between the states of the weather, although the occurrence has by no means the invariability of the sequence we observe between day and night. Hence, the fundamental assumption of the phenomenologists, that our observation of 'invariable sequence' is the basis of our concept of 'efficient causality' is opposed to fact. In accordance with their principle, the phenomenologists must maintain a parity in all cases of invariable sequence. We, however, do not judge the cases to be the same. There must, then, be some other reason why we judge a causal connection to exist between phenomena, between things and events.

Besides this, we clearly distinguish between *conditions* and causes, even if there be an invariable succession between them. We know by experience that we are unable to see objects except in the presence of light. In the dark all objects are invisible; light must first be admitted before we can see. There is an invariable sequence between the presence of light and the seeing of objects. According to the phenomenologists' principle, therefore, we should judge that

light is the 'cause' of vision, because its presence invariably precedes vision. But we do not so judge. We consider light to be the *condition*, not the cause, of vision, although vision must always 'follow after' the admission of light in sound eyes. And so it is with all 'conditions.'

It is entirely untrue to assert that we obtain our concept of cause and effect from the observation of the frequency of an occurrence through habit and the association of ideas. We judge of the presence of causality even in *single cases*. When the first steam engine, or the first telephone, or the first automobile, went into operation, no one waited for the hundredth or thousandth appearance or operation in order to apply the principle of causality; this was done immediately. Similarly, when an accident or disaster occurs, we do not wait until it occurs frequently before we think of cause and effect; we look for the causal connection as soon as it occurs. On the other hand, though we see a million automobiles follow each other down the highway, we never think of the one being the cause of the other, due to association of ideas or habit.

Hence, mere sequence, no matter how frequent and invariable, is not the principle which forces us to accept the concept of efficient cause and causal connection as valid in nature. The *facts* themselves compel our *reason* to judge that the relation of cause and effect exists between things.

OUR EXPERIENCE PROVES CAUSALITY. A CRITICAL ANALYSIS OF OUR internal states and of external nature convinces us of its reality.

Internal consciousness is an indubitable witness to the fact that our mental activities not only take place in us, but that they are also produced by us. Such are the activities of thinking, imagining, desiring, willing. They are clearly observed to be 'produced' by ourselves, and this production is observed to be due to *our own action*, so that their existence is intrinsically dependent on this productive action. Thus, we are conscious that we deliberately set about to solve a certain mental problem by combining ideas into judgments, judgments into inferences, and a whole chain of inferences into an extended argumentation. With the help of our imagination we work out poems, essays, melodies, pictorial scenes, machines, etc., before they ever appear outside the mind. We desire certain things and consciously will them; and we are fully aware that we are the responsible agents of these desires and acts of the will, because we produce them by direct action. No one can deny these facts; they are present for anyone to observe. But if the conscious knowledge of ourselves as the active agents in the production of these internal activities is unreliable and false, all our knowledge, of whatever character, must be adjudged an illusion, because knowledge rests ultimately on the testimony of consciousness. In that case, however, universal skepticism is the logical outcome, and that means the bankruptcy of all science and philosophy. Hence, our consciousness is a trustworthy witness to the fact of efficient causality within us.

External experience proves the same. We speak. Language is an external expression of our internal ideas. It

is impossible for us to doubt that we actually produce the sounds of language which express our own thoughts. We *intend* to express these thoughts in conversation, and we actually *do*; and we are conscious of the fact that we are the agents in this process. If I am a painter, I set up my canvas, mix the paints, apply the colors, and with much effort project my mental images upon the canvas in form and color; I know that all this is not a mere 'sequence of events,' but a production of something in virtue of my own actions. So, too, if I take pen and ink and Write something on paper, I not only perceive one word following the other, but I am also convinced beyond the possibility of any rational doubt that I am the 'author' of the words appearing on the paper. Neither Hume, nor Mill, nor any other phenomenalist, disclaimed the authorship of the books which appeared in their name, nor would they refuse to accept royalties from their publishers on the plea that they were not the efficient causes of these books.

Again, we are convinced that many bodily actions are of a *voluntary* nature. I move my hand, my arm, my head, and I know that these members move because I make them move. If I am set for a sprint, and the gun goes off, I jump into action. But I am conscious that there is not a mere sequence between the shot and my running; and I am also conscious that the shot does not make my limbs move so rapidly: it is I myself who decide to run and who deliberately produce this action of running. This is all the more obvious to me, when I compare this sort of action with the action of the heart or of the liver, etc., over which I have no control. I clearly distinguish between 'sequence' and

‘causality.’ Hume, as we have seen, claims that we cannot know of this causal connection between our will and our bodily movements, because we cannot ‘feel’ the energy involved in this operation. This merely proves that we do not observe the *whole* process. Of the fact of causation itself we are most assuredly aware, and we are also aware of the *exertion* and *fatigue* involved in producing these effects; but if we ‘produced’ nothing, or if there were no energy expended in the production (for instance, in walking, working, running, making a speech, etc.), why should we feel exertion or fatigue? And thus our external experience also testifies to the fact that we ourselves are efficient causes which produce definite effects.

In order to disprove the opponents’ contention, no more is required than to prove a *single case of causality*. We could, therefore, rest our case with the above argument taken from the internal and external experience of our own selves. However, we contend that the existence of other efficient causes in nature is also capable of proof.

REASON DEMANDS EFFICIENT CAUSALITY IN NATURE. IF REASON demands that we admit the existence of efficient cause acting in the universe, the philosopher cannot refuse to accept the verdict of reason, because science and philosophy are based on the operations of reason. Now, if I am convinced beyond doubt that I am the cause of the picture I paint, what am I to conclude, when I see someone else paint a picture? I must conclude that *he* is doing what *I did*, when I went through the same series of actions. Of

course, all that my senses can observe is a 'sequence' of actions; *my reason*, however, demands that he, too, must be the 'producer' of his picture, just as I am of mine. This is common sense and sound logic. And the same principle applies to all actions performed by others, when I observe them doing the same things that I do or have done: if I am an efficient cause, they must be efficient causes for the same reason. There is a complete parity between my actions and their actions, and so I know, through a conclusion of reason, that real causality exists in nature in these and similar cases.

It is only a short step from instances of such activities to *productive activities in the world* at large. A farmer places seed into the soil. After a period of time it sprouts, grows, and eventually matures into an abundant harvest. Here something new has originated. And so with animals and men. We were not here a hundred years ago; but we are here now. We perceive new living beings coming into existence daily. They are new realities. But if they did not exist always and do exist now, they must have *received existence*. Consequently, they must either have given themselves existence, or some other being did. In either case their existence is a 'produced' existence, a 'caused' reality, because they were brought from nonexistence to existence. That, however, which exerts a positive influence through its action in the production of another, is an efficient cause. Here again, scientists admit the thing, though some of them will not admit the name. In general, of course, scientists do not deny the existence of efficient causality.

Efficient causes, therefore, exist in nature. We must, then, reject phenomenalism as false and accept efficient causality as the only adequate interpretation of the facts as observed.

THE PRINCIPLE OF CAUSALITY

The Principle of Causality is formulated in a variety of ways: Nothing happens without a cause; whatever begins to exist must have an efficient cause for its being and existence. One might put it into the following form: *Whatever passes from a state of non-existence into a state of existence, must have an efficient cause for its existence.* This latter formulation includes every kind of real production, whether absolute or relative. A real production is *absolute*, if the total being passes from non-existence to existence without being produced out of the potentiality of pre-existing matter; this is 'creation.' It is *relative*, if the being is produced out of the potentiality of preexisting matter, or if it passes from one kind of being into another kind of being; this is substantial or accidental 'change.' In either case the principle demands an efficient cause to account for the real production.

The validity of the Principle of Causality has been rejected by only a few philosophers. Among these is *Hume*. He says:

"The true state of the question is, whether every object, which begins to exist, must owe its existence to a cause; and this I assert neither to be intuitively nor demonstratively certain."⁵ The position of Hume and of the

phenomenalists is logical, when we consider that they deny the existence of efficient causes in general and admit nothing but an invariable sequence of events in time and space.

The majority of scientists admit that there must be a cause for every effect. In this sense, the Principle of Causality is the basis of all sciences. Unfortunately, however, for the interests of harmonious thought and understanding between philosophers and scientists, the latter at times understand by the 'Principle of Causality' something different from the traditional interpretation as given above. A perusal of the writings of modern physicists might lead the unwary reader to the view that these scientists reject, or at least doubt, the principle that every effect must have a cause. They speak of the necessity of 'reformulating' or 'reinterpreting' the 'Principle of Causality.' Some even assert that its validity has been disproved by modern physics. A careful examination of their views, however, will show that they are speaking of the purely *scientific*, not philosophic, Principle of Causality.

What is the *scientific Principle of Causality*? Briefly, it can be stated thus: When a future event can be predicted with complete certainty from the occurrence of a previous event, they are connected in such a manner that the future event is caused by the previous event. The *predictability* of the future event is the test or criterion of causality. This does not mean, of course, that the future event is considered to be causeless, if it cannot be forecast with accuracy by the scientist; it merely means that the scientist in that case cannot be certain which particular event is the

particular cause of such and such a particular effect. The scientist, therefore, attempts, with his Principle of Causality, or predictability, to *deduce* from a present event the existence of a future event, so that he can conclude *from cause to effect*: if the cause is given, what effect must follow and can be predicted? It will be seen from this that the 'scientific' Principle of Causality is quite different in meaning and scope from the 'philosophic' Principle of Causality. The 'philosophic' principle argues the other way around, namely, *from effect to cause*; if a being passes from nonexistence to existence, it must be a 'produced' being (effect) and as such demands an adequate efficient cause to bring it to existence. While the scientist is interested in deducing a specific effect from a specific cause, the philosopher is interested in discovering whether any and every effect must have a cause.

It would be wrong, therefore, to think that the scientists are in opposition to the philosophers regarding the validity of the Principle of Causality in its *philosophic* meaning. The scientists merely quarrel among themselves about the validity of their own 'scientific' principle, namely, whether effects can be accurately predicted from a scientific knowledge of the physical causes. Their question does not affect the question of the philosophic Principle of Causality in its traditional meaning.⁶

After these preliminary remarks, we must now turn to the problem and ask ourselves: Must every being passing from non-existence to existence, whether relatively or absolutely, be brought to existence through the active influence of an adequate efficient cause? The answer is

affirmative. An analysis of the ideas contained in the Principle of Causality will make the principle evident. In other words, the Principle of Causality is an *analytical principle*, independent of observation and the inductive inferences of science.

By the very fact that a being passes from non-existence to existence, it is assumed and stated that at first it was *nonexistent*. In that condition it was as such only *possible*, i.e., capable of existing. In this state of possibility the 'act' or perfection of 'existence' was not present in any form within the possible being; otherwise it would have been existent at the very time it was non-existent, which is impossible because contradictory. If and when this non-existent but possible being passed into a state of existence, it must have received the act of existence from somewhere and someone. Now, there are only three possible ways in which this being could have received its act of existence: either it received it from '*nothing*,' or from *itself*, or from *some other* being.

It is impossible that it could have received existence *from nothing*.' Since 'nothing' possesses no entity or existence within itself, it cannot give anything and cannot account for anything. If this possible being depended on 'nothing' for its existence, it could never receive the act of existence and would remain forever merely possible, i.e., non-existent. Hence, it could not pass from non-existence to existence. But the supposition is that it did become existent. Consequently, it did not receive its act of existence from 'nothing.'

Could this possible being have received existence *from itself*? It could not. A possible being, from the standpoint of physical actuality and physical entity is nothing; this lies in the fact that it is only a *possible* being. As a possible being it is as yet in a condition of non-existence, and it becomes actual by receiving the act of existence. If it were to give itself existence, it would be necessary that it *produce itself*. A being, however, that does not as yet exist and is actually nothing, cannot produce anything, least of all itself. This is evident. To 'produce' would mean to 'act, before it 'exists'. would mean to 'exist,' because no being can 'act' before it 'exists.' Hence, under the above supposition it would exist, because it acts and produces; and it would not exist, because its existence is assumed to be the effect of its own act. That is, however, impossible, because it involves a contradiction: it would exist and not exist at the same time. Consequently, a being that passes from non-existence to existence cannot receive this existence from itself.

The sufficient reason, why a possible being passes from nonexistence to existence, is not found in 'nothing,' nor is it found in this possible being itself. But it is supposed to pass from non-existence to existence. Hence, by a process of elimination, it is clear that *some other being* must give to it the act of existence. To 'give the act of existence,' however, means to *produce* it by a positive influence. If it did not exert any 'positive influence,' it would not *do* anything and could not give anything; but in that case nothing would happen to the possible being, and the latter would remain in its condition of mere possibility, which is non-existence. This other being must, then, be an *existing* thing itself and

give existence to the possible being by means of a *positive influence*. But to produce a being, i.e., to bring it from non-existence to existence, by the positive influence of its own action, is the definition of an *efficient cause*.

We have thus established the truth of the Principle of Causality: Whatever passes from non-existence to existence, must have an efficient cause for its existence.

AXIOMS REGARDING EFFICIENT CAUSES

Cause and effect are proportionate. The effect cannot be greater than the cause producing it. Otherwise a part of the effect would be without a cause, and that is contrary to the Principle of Causality. Again, the cause cannot have an actually exerted causality which is greater than is required to produce the effect. Otherwise the cause would (partly) not be a 'cause,' since that part of its action would not produce any effect.

No effect can be more perfect than its adequate cause. This is obvious. Otherwise there would be an effect, or part of an effect, without a cause to produce it and give it existence. This would be in violation of the Principle of Causality.

The cause must contain within itself the perfection of the effect. No being can give what it does not possess. Hence, the cause must contain the perfections of its effects either formally, virtually, or eminently.

Nothing can come from nothing; ex nihilo nihil fit. The meaning is: whatever happens must have an efficient cause to account for its happening. Nothing has nothing to give;

therefore, it cannot produce anything. This follows from the Principle of Causality, as just explained.

Every agent acts in a manner similar to itself. Action flows from the nature of the agent. Since the action depends on the nature of the agent, the nature cannot give rise to an action which would be at variance with itself: the agent, therefore, can act only in a manner similar to its nature, i.e., to itself. For this reason the effect must also, in some way, resemble its cause, otherwise the cause would not have contained the perfection of the effect.

Action follows being; agere sequitur esse. All actions are the exercise of the operative powers of a thing. These operative powers proceed from the nature or being of the thing. Hence, the action of a thing must be proportionate to the being and follow the manner of this being.

SUMMARY OF CHAPTER XXII

When scientists speak of physical causes, they do not always mean efficient causes in the philosophic sense. As philosophers, we are interested in the latter.

1. *Cause, Condition, Occasion.* The nature of efficient cause has been explained in the foregoing chapter. A *condition* is something required in order that an efficient cause can act, but it does not contribute any positive influence toward the production of the effect itself. An *occasion* is a circumstance or combination of circumstances which affords an opportunity for an efficient cause to act. They differ from an efficient cause in this that the latter through its own action produces the effect.

2. *Kinds of Efficient Causes.* There are a number of classifications, depending on the different standpoints taken as the basis of division.

- *First Cause and Second Cause.* The former is one whose causality is absolutely independent of any other cause, and on which all other causality depends; this is God. Second causes are those whose causality is dependent on some other cause or being; such are all creatural causes.
- *Physical and Moral Cause.* A 'physical' cause is one which produces an effect by its own direct action. A 'moral' cause is one which inclines a free agent to act.

- *Principal and Instrumental Cause.* A 'principal' cause is an efficient cause which produces an effect in virtue of its own power. An 'instrumental' cause is an efficient cause which produces an effect in virtue of the power of another cause.
- *Cause per se and Cause per accidens.* A cause is a cause *per se*, if it has the natural tendency to produce a particular effect or, if it be a free agent, if it intends to produce it. It is a cause *per accidens*, if it has no natural tendency to produce a particular effect or if it does not freely intend it.
- *Proximate and Remote Cause.* It is 'proximate,' if it produces its effect directly, in virtue of its own action, without using the action of an intermediary cause. It is 'remote,' if it produces its effect through the action of an intermediary cause or causes.
- *Total and Partial Cause.* It is the 'total' cause, when the entire effect is produced by its action; it is the 'partial' cause, when only a part of the entire effect can be attributed to it.
- *Univocal and Equivocal Cause.* A 'univocal' cause is one which produces an effect similar to itself in nature. An 'equivocal' cause is one which produces an effect dissimilar to itself in nature.
- *Necessary and Free Cause.* It is 'necessary,' when it is determined by its nature to produce a certain effect, provided the requisite conditions are present. It is 'free,' when it is not compelled to act,

even though the requisite conditions for action are present.

3. *The Existence of Efficient Causes.* There are efficient causes in nature. The phenomenologists claim that all we can know is an invariable sequence of events in time and space. *Kant* considered efficient causality to be merely a mental category. The occasionalists maintain that God alone is an efficient cause.

Kant's assumption, that we cannot know any things-in-themselves, is wrong, because we certainly know about 'other minds' besides our own. The phenomenologists' assumption is wrong, because we distinguish clearly between sequence and causality.

We prove the existence of efficient causes from our *experience, internal and external*. We are conscious of producing our own acts of thinking, imagining, desiring, willing. We are also conscious of actively producing things through external actions of our body. Reason demands that we conclude to a similar causality, when we see others do as we do; and it also demands causality for the origination of new realities.

4. *The Principle of Causality.* It is formulated: Whatever passes from non-existence to existence, must have an efficient cause for its existence. It is an analytical principle. Such a being must obtain its existence either from 'nothing,' or from itself, or from another being. Not from '*nothing*'; because 'nothing' has no existence to give. Not from *itself*; because to produce itself it would have to act, and to act presupposes existence. Hence, it must receive

existence from *another*. But for another to produce a being, so that it passes from non-existence to existence, means that it is an efficient cause.

5. *Axioms Regarding Efficient Causes*. Cause and effect must be proportionate; no effect can be more perfect than its adequate cause; a cause must contain within itself the perfection of the effect; nothing can come from nothing; every agent acts in a manner similar to itself; action follows being.

Chapter 23

FINAL CAUSALITY

THE EXISTENCE AND NATURE OF *FINAL* CAUSES IS ONE OF THE most controverted points in the history of philosophic thought. The prevalence of materialistic and positivistic views in modern times has accentuated the controversy. Materialists and positivists attack the validity of the concept of 'final causes.' Much of this opposition is due to bias, because the doctrine of 'final causes' seems to point too obviously toward a Supreme Intelligence as a directing influence in the physical world. The question, therefore, is important and warrants a closer inspection.

THE KINDS OF FINAL CAUSES

The general concept of a 'final cause' has already been treated in a former chapter (Chapter 21). Here we must go more into detail as to the various kinds of final causes.

Intrinsic and Extrinsic Final Causes. The causality of a final cause is said to be *intrinsic*, if the action producing a definite effect is the result of a being's *natural tendencies*. A conspicuous example of intrinsic finality is the natural tendency present in the germ-plasm of the organic being to

develop into a specific kind of organism. The germ-cell has a very definite direction in its developmental action. The fertilized ovum of man, for instance, grows into a body which is distinctly human in structure and characteristics, gradually developing the requisite organs and parts even before they can be of any immediate use; such are the head, heart, brain, lungs, nerves, ears, eyes, mouth, stomach, hands, feet, intestines, sex organs, etc. The finality of development is not impressed upon the germ-plasm from without, but is 'intrinsic' to it, because the tendency to develop in this manner is present within the cell itself and the entire action proceeds from the cell itself as from the producing agent. That is why the human ovum never tends to produce the body of a horse or a mouse or any other animal, but only the body of a human being. The same applies, of course, to any other organic being, whether plant or animal.

The causality of a final cause is said to be *extrinsic*, when it is *impressed* upon a being by some *outside directive force*. The finality given to a bowling ball, as it speeds toward the pins, is extrinsic, because it does not lie in the nature of such a ball to move in this particular manner and direction; this action of the ball is imposed on it by the player. So, too, the direction given to a bullet by a sharpshooter aiming at an enemy soldier, wounding or killing the latter, is obviously extrinsic to the bullet, because the bullet as such has no natural tendency to go anywhere in particular.

Final causes are classified also according to the *different ends or purposes* which an agent may have in view, when

exerting its productive activity. The 'end' or 'purpose' is 'that for the sake of which' an agent or efficient cause acts, and therein consists the causality of the final cause. Hence, a classification of the various kinds of ends or purposes will also be a classification of the various final causes.

The End Which and the End for Which (Whom). The former is the *good itself* which is striven for as the end to be realized through the action. When a man, for instance, goes about building a house, it is the house itself which is the end he has in view as the result of his efforts in building. When a physician treats a patient, so as to restore his health, this health of the patient is the 'end which' he intends as the effect of the treatment. The *end for which* (or whom) is the *thing* or *person* that is to benefit by the acquisition or realization of the 'end which' is acquired or realized. When a man builds a house, he may build it as a home for his own family or he may build it to sell at a profit; both purposes are the 'ends for which' the house is built. The physician may have as his 'end for which' he cures a patient the payment of a fee or the increase of his medical reputation.

Proximate End and Remote End. Whenever there is a question of proximate and remote ends, two or more ends are always implied, with a relation between them of nearness or remoteness concerning the final result intended. An end will be the *proximate end*, if it is referred to some ulterior end, but has no other end referred to itself. Thus, when a physician gives his patient some medicine, the immediate or proximate end of this medicine is the health of the patient; and when a man builds a house, the immediate or proximate end is the completed house itself. An end will

be a *remote end*, if one or more other ends are referred to it. And this remote end will be either an 'intermediate' or an 'ultimate' end. *Intermediate* this remote end will be, if one or more ends are referred to it, and it is itself referred to some ulterior end. This will be the case, for example, when the physician wishes to restore the health of the patient (which is his proximate end) for the sake of the fee which he will thereby acquire (intermediate end), so that he can safeguard the future of his family (ulterior end); or when a man builds a house (which is his proximate end), in order to have a comfortable home for his family (intermediate end), so that his family may enjoy earthly happiness (ulterior end). *Ultimate* this remote end will be, if it has one or more ends referred to itself, while it is not itself referred to any other end. This ultimate end may again be either 'relatively' or 'absolutely' ultimate. It is *relatively ultimate*, when it is the last purpose in some particular line; for example, the relatively ultimate end of the physician's work may be a life of affluent retirement in consequence of his amassed wealth, and for the builder of a house it may be the desire of a happy family life. It is *absolutely ultimate*, when it is the last purpose in every line, so that no ulterior end or purpose can be conceived; this, for the physician and builder and for all creatures, is the greater glory of God.

Primary End and Secondary End. An end is said to be the primary or principal end, when it is the main one among two or more which actuate an agent and is sufficient of itself to make the agent act. Thus, the fulfillment of his social duty may be the principal end a physician has in view in his medical practice; the primary end for a man building

a house may be the comfort of his family. An end is said to be *secondary* or accessory, when it is intended together with a primary end, without, however, exerting the same potent influence on the action of the agent. For example, the physician may also strive for fame and money besides the fulfillment of his social duty; and the builder may also intend the personal enjoyment of the lake view which his house affords.

End of the Act and End of the Agent (finis operantis, finis operantis). By the end of the act we understand the purpose which is present in the act itself and which the act tends to realize because it is this particular kind of act. Thus, the 'end of the act' of healing on the part of the physician is the restoration of the 'health' of the patient; and on the part of the builder it is the 'house' being built. By the end of the *agent* we mean the purpose which the agent itself (himself) has in performing this particular act. For instance, the 'end of the agent' for the physician in healing his patient may be the fulfillment of his duty, or money, or fame, etc.; the 'end of the agent' for the builder may be his own comfort, or the comfort of his family, etc.

Natural End and Supernatural End. We speak of a *natural end*, if it lies within the tendencies and powers of the nature of an agent to strive for this end and to realize it. The physician working for the cure of his patient and the builder constructing his house have a natural end in view. An end is supernatural, if it lies beyond the tendencies and powers of the nature of an agent to strive for this end and to realize it. For instance, that the physician and builder

strive for divine grace in their labors, in order to obtain eternal happiness, is a supernatural end of their efforts.

THE EXISTENCE OF FINAL CAUSES

Are there really final causes in nature? Is there finality in the universe? Do things and beings act *in order* to realize some definite *end* and *purpose*? Or, are there merely efficient causes with their effects in nature? Whoever affirms the existence of finality and final causes in the world, advances a *teleological* or purposive explanation of phenomena (τέλος, end, purpose). One who denies finality (teleology) and final causes in nature and asserts that all effects are due to active agents and their powers without any end or purpose directing their activity, is the advocate of a *mechanical* explanation of all things.

Materialists, of course, are mechanists; their theory does not admit of any intelligent foresight working toward the realization of a definite end or purpose, and consequently they must deny the existence of final causes throughout all nature. To them the world consists but of matter and blind energy. *Positivists*, *agnostics*, and *empiricists* deny the possibility of knowing anything beyond the data of sense-perception; hence, since all causality is to them unknowable, final causes are also unknowable and unacceptable. According to these philosophers, final causes are fictions of the mind which man in his ingenuousness carries out into nature; in reality the activities of beings show no directive principle and no intentional effects. Kant and his followers also deny real finality; they consider, as

was explained in the preceding chapter, 'causality' to be merely an *a priori* mental form, without objective value in nature.

In opposition to these we maintain the existence of *finality* or *teleology* in nature. This means that things are not only efficient causes, but are efficient causes with a definite direction in their action: *they tend to realize definite results*. Ontology is concerned with establishing the *general fact* that there are final causes, no matter in what form, and that the concept of finality and final causes has *objective value* and is not a mere fiction of the mind. As long as it can be proved that final causes exist at all, i.e., that some things are influenced in their productive action by ends and purposes, the existence of final causes must be considered as established.

The *proof* is not difficult. We find final causes at work in intellectually conscious, in sentiently conscious, and in unconscious, beings. We mean to prove that there are beings in each of these three groups which act with definite ends or purposes in view, so that their productive activity is positively influenced by the effects which they intend to realize in the future.

FIRST, THEN, WE FIND FINAL CAUSES AT WORK IN *INTELLECTUALLY conscious beings*. Such a being is man. It takes but a little reflection to see the truth of the statement that man acts under the direction of ends and purposes. When a farmer plows his field and plants seeds in the springtime, he does his work with a definite end in view: he wishes to harvest an

abundant crop in the future, and this intention determines the time, place, manner, and duration of his labor, etc.

In fact, it is the exception that man acts without a definite end in view. The entire structure and operation of industry, business, commerce, art, invention, labor, governments, etc., is the result of a host of actions, all of which are directed and dominated by definite ends and purposes. All the activities of peace and war are based upon final causes. It is only the somnambulist, or the insane, or the idiot, who acts without a conscious rational end in view. Intellectually conscious beings, therefore, act in consequence of final causes or purposes, and this happens from morning until night throughout the length of their life. That this is really the case, is evidenced by the direct testimony of our own consciousness; and the validity of this testimony cannot be denied or impugned without destroying the foundations of all knowledge, science, and philosophy.

That these ends and purposes actually *influence* our productive actions in a positive manner, is obvious. The examples mentioned above show this conclusively. Nothing more is required as a proof for the existence of finality and final causes in *some form*. It proves that the concept of ends and purposes as 'final causes' is valid and legitimate and not merely a fiction of the mind. For the sake of completeness, however, we will extend the argument to the remaining two groups of beings.

We also find final causes at work among *sentiently conscious beings*. Brute animals are such beings. Their actions manifest finality. When a cat watches at the hole in

the floor with unswerving eyes, crouches with tensed muscles, chases the mouse that unwisely comes forth, pounces upon it with exposed claws, and then devours it, is this not done for the purpose of catching her prey? When a bird flies about, seeks bits of string, feathers, straw, and twigs, brings them together to a certain tree, and then shapes them with a co-ordinated sequence of apt motions into a nest, is this not done for the purpose of fashioning a nest? Animals may not (and for that matter, do not) understand the 'rationality' of their actions, but they certainly *perceive* things, *desire* them, and *strive* for them. This is finality, or purposive action, pure and simple. Hence, sentiently conscious beings also act in consequence of final causes determining their productive actions.

Finally, there are final causes at work among *unconscious beings*. Such are the chemical compounds and physical bodies in the world at large. Here, naturally, the existence of final causes is not so obvious. It is quite evident, of course, that inorganic beings can have no knowledge of any good and in consequence of this knowledge strive for it. The question is not, however, whether they 'knowingly' strive for ends, but whether they do, *as a matter of fact*, tend to realize definite results in the future as the effects of their activities, so that these activities have a definite *direction* given to them in virtue of the effects striven for. This, we contend, is actually the case.

Inorganic beings are governed by *natural* and *necessary* laws, to which they are subject at all times. Chemical affinity, for instance, is a selective attraction existing between different kinds of elements and it controls the

activity of the elements and their compounds throughout all chemical changes. This affinity, however we may conceive it in its nature and operation, is the expression of a natural *law*. But what is a natural law, if not the expression of the *inner tendencies of the nature* of such things? Chemical affinity is not a fortuitous event, occurring sporadically here and there and now and then, but a constant and regular occurrence which takes place without exception, provided the conditions are the same. Hence, elements tend to form specific compounds by means of a *selective tendency*, and this selective tendency runs through a *set series of changes*, until it realizes the compound as the end-result of its activity; this done, its activity ceases.

The finality existing in unconscious beings is observed more clearly in the tendencies of *vegetant* beings, as manifested in the growth and development of their *structural forms*. Attention has already been called to the 'intrinsic finality' existing in the human ovum. This applies with equal force to every *organism*, whether man or brute or plant, in the vegetative functions of its growth, beginning with one original cell and developing into a completely mature individual. Growth is an unconscious operation of living tissue. Notwithstanding the unconsciousness of the process, there is a very distinct tendency and direction in it toward a specific result. Somehow, the germ-cell contains within itself the design of the mature individual of a particular *specific type*, and it *tends* to develop this type under all conditions. The individuals vary in height, size, weight, and characteristics within certain limits; but they develop according to a well-defined plan, so as to carry out

the pattern of the type. This is so obvious a fact, that the theory of evolution demands vast periods of time for the transmutation of one species into another. The development of the germ-cell into an individual of a specific type is constant, regular, natural; it is the result of an *internal driving power* present in the germ-cell and prolonged through the whole life history of the organism.

As the result of this internal principle of development, billions of cells are formed, combine together into various kinds of structural members, tissues, and organs, placed in mutual relationship as to position and function. These members, tissues, and organs have their own individual kind of activity, but they are co-ordinated and interdependent in such a manner that the well-being of the organism *as a whole* is the evident purpose and tendency of all combined. This tendency to produce and maintain the type-individual is an immense fact of nature which can be adequately explained only through *finality* and *final causes*, because the original cell has the positive tendency to produce a definite effect *in the future*.

FINALITY AND FUTURITY

There is a serious objection against the concept of final causes in general and against the concept of finality in unconscious beings in particular. In speaking of 'ends' and 'purposes' as final *causes*, are we not doing violence to the concept of 'cause'? A cause must really assist in the production of a thing through a positive influence. But surely, no being can assist in the production of something

unless it really exists. The end or purpose, however, does not reach existence until the entire productive action is terminated, because it is effected or realized only as the result of the action. Since, then, the end or purpose is really non-existent as an entity at the beginning of the productive action, it seems impossible for it to exert any causality in the production. For instance, the physician intends to restore the health of a patient; this 'health-to-be-restored' is the end or purpose he has in view with his treatment; health itself occurs only at the termination of the treatment and is non-existent at the beginning of the treatment: then how can this 'health-to-be-restored' influence his action (the restorative treatment) and be a *real cause*?

It is true that the end or purpose intended (e.g., the health of the patient) does not exist in the *physical order* in the beginning; as such, therefore, it cannot exert any 'physical action' in the production of the result. But the end or purpose exists in the *intentional order*, namely, as a 'design' or 'plan' held constantly in view. As such it determines the agent (e.g., the physician) to *act* and also determines the manner of action (e.g., the treatment). The presence of this end or purpose sets a long chain of actions in motion, bringing into existence a decided change of events. And this means that the end or purpose is a real final cause in the true sense of the term.

But would the end or purpose, since it determines the action from the beginning, not presuppose some sort of *knowledge of the end or purpose* on the part of the agent, in order to strive for its realization *in the future*? Assuredly it does. With intellectually conscious beings this involves no

difficulty, because they possess a faculty of knowledge. With unconscious beings and inorganic and vegetative activities the situation is entirely different. Inorganic beings and plants have no faculty of knowledge, and the vegetative functions of brutes and men are performed unconsciously; in them the tendency to produce definite effects in the future is the *result of their nature*, which directs their activities without any knowledge of the process on their part. Then how can one speak of an 'end' or 'purpose' which is supposed to be present from the beginning and work 'in order to' realize a future effect according to a certain 'plan' or 'design'? How can their nature direct a course of action of which it has no knowledge? Whence this 'tendency' and 'determination' intrinsic to their nature? The answer is that such finality in action certainly presupposes a *conscious knowledge* of the end or purpose striven for. Since, however, inorganic activity and vegetative function is not the result of conscious knowledge on the part of these beings themselves, but is the outcome of an intrinsic tendency of their nature, the finality of their actions ultimately postulates a *creative Intelligence* which intended these future results for them and gave them a nature which spontaneously tends to realize its intrinsic ends and purpose. Any other hypothesis will not account for the evident facts. This is also the only logical explanation for the *instinctive* actions so strikingly manifested in the animal kingdom.

However, no matter what we may consider to be the proper explanation, there can be no question about the *fact* that beings do act for definite ends. Final causes, therefore,

do exist in some form among beings; and the concept of 'final causes' is thus not an idle fancy, but is *objectively real* in nature.

AXIOMS CONCERNING FINAL CAUSES

The end or purpose is the cause of all causes. The material cause is determined by the formal cause; the formal cause is determined by the efficient cause; and the efficient cause is determined in its action by the end or purpose in view, i.e., by the final cause. Hence, the final cause determines the other causes and is thus the cause of all causes.

Every agent acts for an end. Man acts because his will strives for some apprehended good. Animals, plants, and inorganic beings strive for things in virtue of the tendencies inherent in their nature. Consequently, all beings act, consciously or unconsciously, for an end or purpose.

Who intends the end must intend the means. Whoever effectively intends an end, must strive to realize it. But if one cannot realize it except through the use of certain means, one must evidently also intend these means; otherwise one would not effectively intend the end itself. It follows from this, that whoever uses certain means in order to attain the end, is responsible for the means which he uses in the attainment of this end. Hence, a good end will not justify immoral means.

The end is first in intention, last in execution. The end or purpose is the result to be achieved through the productive action in the future; and when it is achieved, the action ceases. But in order that the action can tend to produce this

result, the action must be determined from the very beginning by this effect held in view as an end or purpose. Hence, the end is first in intention and last in execution.

The end is, in itself, nobler than the means. It is the end which determines the means to be used; the means do not determine the end. The means are used to acquire the end. Hence, the means are not striven for on account of their own goodness, but rather for the possession of the goodness present in the end.

End and means must be proportionate. Obviously. It would not do to attempt to stem a flood with a twig, nor to let loose a deluge in order to drown a fly. Major purposes demand major means, and minor purposes demand minor means. This refers as well to the importance as to the magnitude of the end in view; both demand a corresponding use of means, so as to insure the achievement of the result intended.

SCIENCE AND FINAL CAUSES

What is the attitude of science toward final causes and *finality in nature*? By science we mean the 'scientists.' Their general attitude is one of negative aloofness toward the question. They do not concern themselves about the presence of final causes in nature and make no attempt to decide whether things actually strive with their actions to realize ends and purposes set for their actions as a definite goal which they are supposed to reach. As scientists, they seek to understand the phenomena which occur in nature and then seek for the efficient causes which produce them

through their actions. When they have discovered this causal connection between subsequent and antecedent events, they feel that they have arrived at a *scientific knowledge* of all that science is entitled to investigate and know. Whatever lies beyond this sort of knowledge lies beyond the legitimate field of science. The philosopher may seek to penetrate more deeply into the mysteries of nature, if he can; but the scientist, as a scientist, is content to understand the operations of nature and express its operations in the formula of a physical law.

As scientists conceive science, it is primarily a *method* of investigation, based on *observation* and *experiment*. Whatever is discoverable by this method is a proper object of science. This object alone is of interest to the scientist. Hence, the changes in nature, and the corresponding activities producing them, are the field which science investigates. This means that 'efficient causality,' in a physical sense of the term, are the factors in nature which science can legitimately investigate, so as to correlate its findings in a complete body of demonstrated, scientific truths. Such are the limits of science set by the scientists themselves. Hence, scientists do not interest themselves in the intrinsic, constitutive principles of bodies, such as matter and form (material and formal causes), nor in the intrinsic tendencies of bodily actions (final causes). They are content to accept the nature of bodies as given and to study the actions as observable facts.

No one can quarrel with the scientists, if they deliberately restrict the field of scientific research in this manner, provided they do not overstep the bounds of their

own restrictions. They may *ignore* the question of finality in nature as something outside the scope of their scientific investigation. But they may not, according to the rules laid down by themselves, *deny* the existence of finality in natural beings, without ceasing to be scientists and professing to be philosophers. The question of finality and final causes is a metaphysical question and belongs to philosophy, not to science as limited by the scientists. Consequently, if the investigations of the philosopher demand the existence of final causes as an adequate explanation of natural occurrences, it is not within the province of the scientist as such to dispute or deny their existence and the validity of their concept. Unfortunately, scientists sometimes contend that, because final causes are *not observable*, their existence must be denied. This is a false principle of logical reasoning which, if applied, must do harm to the best interests of both science and philosophy.

Unlike the scientists, the philosopher cannot ignore the problem of final causes and finality. It is his endeavor to discover the truth in things *as far as reason can reach*. He cannot rest content with a knowledge of observable data, but must apply the principles of reason to the data furnished by observation and experiment and seek a *rational interpretation* of the facts in their entirety. It is for this reason that the philosopher attempts to discover all the causes operative in nature. Among these causes are final causes. So far we have established the fact that final causes actually exist, at least in some form and to some extent.

The question is often asked: 'Do ducks fly and swim because they have wings and webbed feet, or do they have

wings and webbed feet in order to fly and swim?’ The scientist would answer: ‘They fly, because they have wings, and they swim, because they have webbed feet’: that is all that concerns the scientist as a scientist. The philosopher, if he agrees with our viewpoint, would answer: ‘First of all, the ducks have wings and webbed feet in order to fly and swim, and then they fly and swim because they have wings and webbed feet.’ The scientist answers by affirming the existence of *efficient* causes, while the philosopher answers by affirming the existence of both *efficient and final* causes.

Those philosophers who deny the existence of final causes in nature (except, perhaps, in the case of man, due to his intellectual capacity of preconceiving an end or purpose for his action), must of necessity contend that *blind forces* rule the world and that all things occur through ‘chance,’ or ‘luck,’ or ‘accident.’ Hence, some attention must be given to the possible existence of such factors in nature.

CHANCE, LUCK, ACCIDENT

Terms like ‘chance,’ ‘luck,’ ‘accident,’ and similar expressions are found in all languages. They show the firm conviction of people that many things happen in this world which are beyond the control of any regulative principle in nature. Such occurrences are, therefore, conceived as happening without being the result of purposive action: no end or purpose and consequently *no final cause determines their course*. What truth is there in this view?

The following are instances of the occurrences which are usually considered to be the result of 'chance' or 'luck' or 'accident.' A man spades his garden, in order to plant some vegetables, and uncovers a hidden treasure of which he had no knowledge. This is a case of 'good luck,' and he is said to find this treasure by 'chance' or 'accident'; it is also spoken of as 'good fortune.' Years after a war, a farmer plows a field which had been the scene of a battle, hits a hidden shell, and is hurt by the explosion. He had 'bad luck' or 'misfortune,' and his injury was the result of an 'accident.' Two cars, speeding along separate highways which cross each other at right angles, meet at the intersection, and a collision occurs. The meeting of the cars was 'by chance,' and the collision was an 'accident.' What is chance, or luck, or *accident*?

The Principle of Causality guarantees that no effect can happen without an *adequate efficient cause* to account for it. 'Chance' results, therefore, must never be understood in the sense that effects occur without a cause: such events would be impossible. But what is meant by chance results is that certain effects are *not intended* by the active agents under these particular circumstances. An effect may be 'intended' by directly *willing* it, if the agent is free in its activity; or it may be 'intended' because a thing has the *natural tendency* to produce a definite effect. Thus, if I deliberately throw a ball, I 'intend' the movement of the ball through the air. Gravity has the natural tendency to bring the ball back to earth; it also 'intends' this downward motion. Neither of these two movements is due to 'chance,' 'luck,' or 'accident.' When, however, a certain effect is not

intended freely or naturally, as just explained, it is said to be due to 'chance,' 'luck,' or 'accident.' For instance, when I throw a ball, and the ball, without my intending it, hits a man on the head, this is an 'accident.' Because, although I freely 'intended' to throw the ball, I did not intend the man's head as the target for my marksmanship; and so, too, although gravity attracted the ball in virtue of a natural tendency and thus 'intended' its downward course, it had no natural tendency to attract the ball in such a manner that it would alight upon the man's head. That the ball struck his head was due to an unfortunate *conjunction of causes* which was intended neither by me nor by nature.

In accidental occurrences *two distinct factors* must be considered. Each efficient cause intends a certain result, either freely or because of a natural tendency, and the causality of the efficient cause is directed and determined by an end or purpose which the efficient cause seeks to realize as the direct effect of its action; the action of each cause is, therefore, intended separately and *independently* of the other, so that there is no concerted action intended by the different causes with relation to each other. The *coincidence* of these separate and independent lines of action, therefore, is not intended by these efficient causes and lies outside the scope of their individual ends and purposes; therein lies the element of 'chance,' 'luck,' and accident,' because no regulative principle controls the meeting of these separate and independent actions: their meeting or conjunction just 'happens.' Accidents thus occur *incidentally* to some intended action.

Aristotle therefore *defines chance*, or luck, or accident (for they mean essentially the same thing) as “the incidental production of some significant result by a cause that took its place in the causal chain incidentally, and without the result in question being contemplated.” And he goes on to say: “Clearly then luck itself, regarded as a cause, is the name we give to causation which incidentally inheres in deliberately purposeful action taken with respect to some other end but leading to the event we call fortunate” [or unfortunate]¹ Aristotle’s observation here is very acute and is borne out by the analysis of an accidental occurrence. Two automobile drivers take their cars out into the country. One drives from east to west, and the other from north to south. Their action is purposeful; each intends to ride, and drives his car in accordance with his purpose. That the two cars, driven at their respective speeds, will meet at the intersection of the two highways at a particular moment and thus cause a collision, is something unforeseen and unintended by both drivers. Hence, the *conjunction* of these two sets of efficient causality is only *incidental* to the purposeful action of each driver and is beyond their knowledge and control.

Since there is no finite controlling factor which brings about this conjunction of efficient causalities, such accidental effects cannot be foreseen and foretold with any degree of certainty, except by God. *Irregularity* and *lack of constancy* are the characteristic marks of events that happen by chance. It follows that events and phenomena, which occur regularly and constantly in nature according to a physical law, cannot be the result of chance; whatever is

constant, normal, and according to type, is contrary to the very concept of chance.

Is the universe, then, governed by *chance or purpose*? The law, order, and harmony manifest everywhere in nature is the best evidence that the universe is governed by *purposeful design*. Aristotle expresses his view on this question as follows:

“In general, the theory [of chance, as the dominant factor in the universe] does away with the whole order of Nature, and indeed with Nature’s self. For natural things are exactly those which do move continuously, in virtue of a principle inherent in themselves, toward a determined goal; and the final development which results from any one such principle is not identical for any two species, nor yet is it any random result; but in each there is always a tendency toward an identical result, if nothing interferes with the process. A desirable result and the means to it may also be produced by chance, as for instance we say it was ‘by luck’ that the stranger came and ransomed the prisoner before he left, where the ransoming is done as if the man had come for that purpose, though in fact he did not. In this case the desirable result is incidental; for, as we have explained, chance is an incidental cause. But when the desirable result is effected invariably or normally, it is not an incidental or chance occurrence; and in the course of Nature the result always is achieved either invariably or normally, if nothing hinders. It is absurd to suppose that there is no purpose because in Nature we can never detect the moving power in the act of deliberation. . . . That

Nature is a cause, then, and a goal-directed cause, is above dispute."²

Nature, of course, has no intelligence of its own and as such cannot select the goal of its action as an end or purpose for which to strive. Nevertheless, intelligence is required in order that nature can be "a goal-directed cause," striving toward the realization of its all-encompassing purpose according to precise laws. Hence, the presence of a purpose or goal in nature demands the existence of a Supreme Intelligence outside itself. One of the most eminent of modern physicists, Max Planck, says: "The most perfect harmony and consequently the strictest causality in any case, culminates in the assumption that there is an ideal spirit having a full knowledge of the action of the natural forces as well as of the events in the intellectual life of men; a knowledge extending to every detail and embracing present, past, and future."³

This "ideal spirit" is God.

SUMMARY OF CHAPTER XXIII

The existence and nature of final causes is one of the most controverted points of philosophy.

1. *Kinds of Final Causes.* The concept of final cause was explained in a preceding chapter.

Intrinsic and Extrinsic Final Causes. The causality of a final cause is said to be 'intrinsic,' if the action producing a definite effect is the result of a being's natural tendencies. The causality is 'extrinsic,' when it is impressed upon a being by some outside directive force.

Since it is the 'end' or 'purpose' which is that for the sake of which an efficient cause acts, final causes are also classified according to the various kinds of 'ends' or 'purposes.' The *End Which and the End for Which (Whom).* The former is the good itself which is striven for as the end to be realized through the action; the latter is the thing or person that is to benefit by the acquisition or realization of the end which is acquired or realized. *Proximate and Remote End.* It is a 'proximate' end, if it is referred to some ulterior end, but has no other end referred to itself; it is a 'remote' end, if one or more other ends are referred to it. A remote end will be either intermediate or ultimate. *Primary and Secondary End.* It is the 'primary' end, when it is the main one among two or more and is sufficient of itself to make the agent act; it is 'secondary,' when it is intended together with a primary end. *End of the Act and End of the Agent.* The former is the end which is the purpose of the act itself; that latter is the purpose which the agent has in

performing the act. *Natural and Supernatural End*. It is a 'natural' end, if it lies within the tendencies and powers of an agent to strive for this end and to realize it; it is supernatural,' if it lies beyond the tendencies and powers of an agent to strive for this end and to realize it.

2. *The Existence of Final Cause*. This existence is denied by materialists, positivists, agnostics, and empiricists; we maintain *finality* (teleology) in nature, at least in some form. This means that some efficient causes *tend to realize definite results*.

Intellectually conscious beings (men) have definite ends and purposes for their action; this is a daily experience, as our consciousness testifies. *Sentiently conscious* beings (brutes) perceive things, desire things, and strive for things; instinctive actions are all purposive. *Unconscious* beings (chemicals and plants) also show finality in their actions: chemical affinity is a selective tendency which seeks to realize definite sorts of compounds; the germ-cells of plants tend toward producing individuals according to the patterns of the specific type.

3. *Axioms Concerning Final Causes*. The end or purpose is the cause of all causes. Every agent acts for an end. Who intends the end must intend the means. The end is first in intention, last in execution. The end is, in itself, nobler than the means. End and means must be proportionate.

4. *Science and Final Causes*. The attitude of scientists toward final causes in nature is one of *negative aloofness* toward the question. They are interested merely in observable phenomena and their causation. Hence, they restrict the field of scientific knowledge to efficient causes

and ignore the possible existence of final causes in nature as being beyond the scope of science.

5. *Chance, Luck, Accident.* The Principle of Causality guarantees that no effect can happen without an adequate efficient cause. But many effects happen by chance, in as much as the *conjunction* of efficient causes and their actions is not always *intended*. Chance (luck, accident) is the incidental production of some significant result by a cause that took its place in the causal chain incidentally, and without the result in question being contemplated. *Irregularity and lack of constancy* is the mark of chance; what happens regularly, constantly, and normally, is not the result of chance. Nature works in a manner which is regular, constant, and normal, because it acts according to laws. Nature, therefore, is governed by final causes, not by chance.

GLOSSARY OF TERMS

Note: In the case of qualified words, always look for the word or noun qualified. For example: in seeking for Absolute Accident, look for Accident, Absolute, etc.

ABSTRACTION. A process in which the mind fixes its attention upon one or the other characteristic of a thing or upon one element common to many things, excluding others which are joined to it in the real order. See. Precision.

ACCIDENT. A being whose nature it is to exist in another as in a subject.

ACCIDENT, ABSOLUTE. An accident which confers a real perfection upon its subject.

ACCIDENT, EXTRINSIC. An accident which does not affect the being of its subject, but modifies the subject's immediate surroundings.

ACCIDENT, INTRINSIC. An accident which affects the being of its subject in some manner.

ACCIDENT, MODAL. The definite disposition or determination of an indifferent and determinable accidental entity in such a manner that it does not confer any positive and new entity upon the substance.

ACCIDENT, RELATIVE. An accident that has its being in a subject only because of the bearing which one thing has to another.

ACCIDENT, STRICTLY ABSOLUTE. An accident which confers upon its subject some positive and new entity.

ACT. Any entity of whatever kind and nature which perfects and determines a thing in its being.

ACT, MIXED. An act that in some form or other has an admixture of potentiality.

ACT, NON-PURE. See Act, Mixed.

ACT, PRIMARY. An act that is the first in a series of acts.

ACT, PURE. An act that is without the least admixture of potentiality.

ACT, SECONDARY. An act that presupposes another act in a definite series, so that it proceeds from a primary act.

ACTION. The exercise or operation of an operative potency. The production of an effect.

ACTIVITY, IMMANENT. The activity through which a living being perfects itself and makes itself the goal for the acquired actuality or perfection.

ACTIVITY, TRANSIENT (TRANSEUNT, TRANSITIVE). The activity which tends to change another object.

ACTIVITY, VITAL. See Activity, Immanent.

AFFECTION. A relatively transient quality which produces, or results from, some accidental sensible alteration.

ALTERATION. The change of a being from one qualitative state to another.

ANNIHILATION. The reduction of an existing being to non-existence.

ATTRIBUTES, TRANSCENDENTAL. The supreme modes necessarily connected with every being, which are different phases of the same fundamental being, but are not explicitly contained in its concept as such.

AUGMENTATION. The change of a being from one quantitative state to another.

BEAUTY. That attribute of a thing in virtue of which the thing pleases when perceived. A blending of the unity, truth, and goodness in a thing, characterized by completeness, proportion, and clarity of presentation in an intellectual-sensuous form, so as to produce a disinterested emotional pleasure in a rational perceiver.

BEING. That which exists or can exist, the existible; whatever is not nothing.

BEING, ABSOLUTE. A being which can be thought of or can exist without reference to another.

BEING, ACCIDENTAL. See Accident.

BEING, ACTUAL. Anything that really exists at the present moment in the physical or spiritual world.

BEING, CONTINGENT. A being whose non-existence is possible.

BEING, CONTRACTION OF. See Contraction of Being.

BEING, FINITE. A being whose reality is limited in perfection.

BEING, IDEAL. Any object in so far as it is known.

BEING, INFINITE. A being which has no limit in its entity or perfection.

BEING, LOGICAL. Anything that has objective being only in the mind.

BEING, NECESSARY. A being whose non-existence is impossible.

BEING, POSSIBLE. Anything that does not actually exist, but is capable of existence.

BEING, REAL. Anything that has, or can have, existence independent of man's actual knowledge.

BEING, RELATIVE. A being which can be thought of or can exist only in reference to another.

BEING, SUBSTANTIAL. See Substance.

CAPACITY, NATURAL. The proximate accidental principle of operation, toward which (operation) it is specifically directed.

CATEGORY. An ultimate and supreme mode of real being; a predicament.

CAUSALITY, PRINCIPLE OF. The principle which states that whatever passes from a state of non-existence into a state of existence must have an efficient cause for its existence.

CAUSE. That which in any way whatever exerts a positive influence in the production of a thing.

CAUSE, EFFICIENT. That by which something is produced.

CAUSE, EQUIVOCAL. A cause which produces an effect dissimilar to itself in nature.

CAUSE, FINAL. That for the sake of which an efficient cause acts.

CAUSE, FIRST. A cause whose causality is absolutely independent of any other cause or being, and on which all other causality depends.

CAUSE, FORMAL. That through which a thing is made to be what it is. Form.

CAUSE, FREE. A cause which is not compelled to act, even though all the requisite conditions for action are present.

CAUSE, INSTRUMENTAL. An efficient cause which produces an effect in virtue of the power of another cause.

CAUSE, MATERIAL. That out of which something becomes or is made. Matter.

CAUSE, MORAL. A cause which inclines a free agent to act.

CAUSE, NECESSARY. A cause which is determined by its nature to produce a certain effect, provided the requisite conditions are present.

CAUSE, PARTIAL. A cause whose action produces only a part of the total effect.

CAUSE PER ACCIDENS. A cause which produces an effect toward which it has no natural tendency, or which the free will (if that be the cause in question) does not intend.

CAUSE PER SE. A cause that has the natural tendency to produce a particular effect or, if it be a free agent, that intends freely to produce it.

CAUSE, PHYSICAL. A cause which produces an effect by its own direct action.

CAUSE, PRINCIPAL. An efficient cause which produces an effect in virtue of its own power.

CAUSE, PROXIMATE. A cause which produces its effect directly, in virtue of its own action, without using the action of some intermediate cause.

CAUSE, REMOTE. A cause which produces an effect through the direct action of some intermediary cause or causes.

CAUSE, SECOND. A cause whose causality is dependent on some other cause or being.

CAUSE, TOTAL. A cause whose action produces the entire effect.

CAUSE, UNIVOCAL. A cause which produces an effect similar to itself in nature.

CHANCE. The causality of agents resulting in effects not intended by the agents under these particular circumstances.

CHANGE. The transition from one positive state of being to another.

CHANGE, PRINCIPLE OF. The principle which states that whatever changes is changed by another.

COMPOSITION, LOGICAL. A union of elements which are neither objectively different in idea nor physically different as things, but merely different in the sense that the one idea contains implicitly and vaguely what the other expresses explicitly and determinately.

COMPOSITION, METAPHYSICAL. The union of elements that are objectively different in idea, but really identical in their physical being as things.

COMPOSITION, PHYSICAL. The union of elements that are objectively different in idea and physically different as things.

CONDITION. Something required in order that an efficient cause can act.

CONTRACTION OF BEING. The reduction or narrowing of the extension of being to its inferiors by means of the addition of some element to the comprehension of 'being,' thereby including some definite beings and excluding others from this extension.

CONTRADICTION, PRINCIPLE OF. It is impossible for a thing to be and not to be at the same time. A thing cannot be and not be something at the same time.

CORRUPTION. A substantial change which makes a substance cease to be.

CREATION. The production of a thing from nothing.

DETERMINATIONS, PRIMARY. Primary determinations of being are those which are transcendental, i.e., those which constitute the most fundamental distinctions of 'being in general' and go beyond all the ordinary classifications of beings.

DETERMINATIONS, TRANSCENDENTAL. Those primary determinations which constitute the most fundamental distinctions of 'being in general' and go beyond all the ordinary classifications of beings.

DISPOSITION. A relatively transient quality which disposes a being temporarily well.

DISTINCTION. The absence of sameness between concepts or things.

DISTINCTION, ADEQUATE REAL. A real distinction between things so that they are distinct in their total being.

DISTINCTION, FORMAL (SCOTISTIC). A distinction, maintained by Duns Scotus, actual on the part of the thing,

as between formality and formality, though not real, as between thing and thing.

DISTINCTION, INADEQUATE REAL. A real distinction in which things are distinct as part and whole.

DISTINCTION. LOGICAL. The absence of sameness between concepts of the same reality.

DISTINCTION, MAJOR REAL. The absence of identity between thing and thing to such an extent that they are distinct from each other as entities.

DISTINCTION, MENTAL. See Distinction, Logical.

DISTINCTION, MINOR REAL. The absence of identity between a thing and its mode.

DISTINCTION, NEGATIVE REAL. A real distinction in which there is a non-entity either on one or on both sides of the distinction.

DISTINCTION, POSITIVE REAL. A real distinction in which the distinct things are real (positive) entities and differ in their entities.

DISTINCTION, PURELY MENTAL. A distinction between concepts of one and the same reality, without a foundation in the object itself for making the distinction.

DISTINCTION, REAL. The absence of sameness between things different in their reality.

DISTINCTION, SCOTISTIC. See Distinction, Formal.

DISTINCTION, VIRTUAL. The distinction between different concepts of one and the same reality, with a foundation in the object itself for making the distinction.

EFFECT. That which is produced.

END (PURPOSE). That for the sake of which an agent or efficient cause acts. See Cause, Final.

END FOR WHICH (WHOM). The thing or person that is to benefit by the acquisition or realization of the 'end which' is acquired or realized.

END, INTERMEDIATE. An end to which one or more ends are referred, and which is itself referred to some ulterior end.

END, NATURAL. An end which lies within the tendencies and powers of the nature of the agent to strive for.

END OF THE ACT. The purpose which is present in the act itself and which the act tends to realize because it is this particular kind of act.

END OF THE AGENT. The purpose which the agent itself (himself) has in performing this particular act.

END, PRIMARY (PRINCIPAL). The main end or purpose among two or more which actuates an agent and is sufficient of itself to make the agent act.

END, PROXIMATE. The end that is referred to some ulterior end, but has no other end referred to itself.

END, REMOTE. An end to which one or more other ends are referred.

END, SECONDARY (ACCESSORY). An end intended together with a primary end, without, however, exerting the same potent influence on the action of the agent.

END, SUPERNATURAL. An end which lies beyond the tendencies and powers of the nature of an agent to strive for.

END, ULTIMATE. An end which has one or more ends referred to itself, while it is not itself referred to any other

end.

END WHICH. The good itself which is striven for as an end to be realized through the action of a cause.

ENERGY, KINETIC. Energy of motion.

ENERGY, POTENTIAL. Energy of position.

ERROR. Disconformity (disagreement) between intellect and thing.

ESSENCE. The act of actuality which perfects and determines a thing in its species; that which makes a thing to be what it is.

ESSENCE, METAPHYSICAL. The sum of the various grades of being which constitute a thing in the abstract concepts of the mind.

ESSENCE, PHYSICAL. An essence as it exists concretely in nature, independent of the mind's thinking.

EVIL. Something that is unsuitable for a natural tendency or appetency. The privation of a required good.

EVIL, ABSOLUTE. The privation of an absolute good.

EVIL, APPARENT. The privation of an apparent good.

EVIL, MORAL. The privation of the proper relation between an action or its omission and the moral law.

EVIL, OBJECTIVE. The privation of an objective good.

EVIL, ONTOLOGICAL. The privation of an ontological good.

EVIL, PHYSICAL. The privation of a physical good.

EVIL, REAL. The privation of a real good.

EVIL, RELATIVE. The privation of a relative good.

EVIL, SUBJECTIVE. The privation of a subjective good.

EXCLUDED MIDDLE, PRINCIPLE OF. A thing either is or is not. Every thing must either be or not be. Between

‘being’ and ‘not-being’ there is no middle or third thing possible.

EXISTENCE. That state of a being in virtue of which it is present as an actuality and not merely as a possibility, distinct from the mind and, if it be a produced being, distinct from its producing cause.

FALSITY (ERROR). Disconformity (disagreement) between intellect and thing.

FALSITY, LOGICAL. The disagreement of the intellect with the thing.

FALSITY, MORAL. The disagreement of speech with thought.

FALSITY, ONTOLOGICAL. The disagreement of a thing with the intellect.

FIGURE. The geometrical quality resulting in a body from the arrangement of its quantitative parts.

FINAL CAUSE, EXTRINSIC. A cause whose causal action is impressed upon it by some outside directive force.

FINAL CAUSE, INTRINSIC. A cause whose action producing a definite effect is the result of a being’s natural tendencies.

FORM. The physical quality resulting in a body from the arrangement of its quantitative parts. See Cause, Formal.

GENERATION. A substantial change which brings a new substance into being through the corruption of another or others.

GOOD. Any reality which suits the nature of the being which strives for it.

GOOD, ABSOLUTE. Anything which is suitable to a being itself, irrespective of other beings.

GOOD, APPARENT. Something that is judged to be good for a being, but is actually not good for it.

GOOD, DELECTABLE. A relative good which gives pleasure and enjoyment to another.

GOOD, DISINTERESTED. A good considered merely as giving perfection, irrespective of any pleasure derived from its possession.

GOOD, METAPHYSICAL. See Good, Ontological.

GOOD, MORAL. A good which has everything demanded of it by the moral law.

GOOD, OBJECTIVE. Anything that is good in itself.

GOOD, ONTOLOGICAL. A thing as good in its very entity or reality.

GOOD, PHYSICAL. A good which satisfies the demand of the nature of a being.

GOOD, REAL. Something that is judged to be good for a being and actually is good for it.

GOOD, RELATIVE. Anything which is suitable to another.

GOOD, SUBJECTIVE. The actual possession of an objective good.

GOOD, TRANSCENDENTAL. See Good, Ontological.

GOOD, USEFUL. A relative good which is desired as a means to acquire perfection or pleasure.

GOODNESS. The suitability of a thing for a natural tendency or appetency.

HABIT. As a quality, it is a comparatively permanent accident disposing a thing well or ill in its being.

HABIT, OPERATIVE. A stable quality disposing a being ill or well in the operations of its faculties.

HABITUS. The condition resulting from clothing, equipment, physical adjuncts, environment; or a condition or state, as expressed by the reflexive verb.

HYPOSTASIS (SUPPOSITUM). A complete and individual substance which has subsistence, i.e., a substance which is self-contained and autonomous (*sui juris*) in its operations.

IDENTITY. A sameness between concepts or things.

IDENTITY, ACCIDENTAL LOGICAL. The logical identity of things based upon the similarity of their accidents.

IDENTITY, ESSENTIAL LOGICAL. The logical identity of things based upon the similarity of their essence.

IDENTITY, LOGICAL. The unity (oneness) of things based upon the same concept of the mind.

IDENTITY, METAPHYSICAL. The real identity of a being, in virtue of which it can absolutely not change in any manner.

IDENTITY, MORAL. The real identity of a being, in virtue of which the change which takes place in its essential being is successive and gradual.

IDENTITY, PHYSICAL. The real identity of a being, in virtue of which it does not change in its essential reality.

IDENTITY, PRINCIPLE OF. Whatever is, is; and whatever is not, is not. Everything is what it is. Everything is its own being. Being is being, and not-being is not-being.

IDENTITY, REAL. The unity (oneness) of things in themselves.

INCAPACITY. An existing faculty in a weakened or unfit condition.

INDISPOSITION. A relatively transient quality which disposes a being temporarily ill.

INDIVIDUALITY. That state of an existing being in virtue of which it is one and non-multipliable.

INDIVIDUALITY, UNITY OF. The unity of a being which is one in itself and non-multipliable.

INDIVIDUATION, ABSOLUTE, PRINCIPLE OF. That intrinsic principle which gives the unity of individuality to an existing being.

INDIVIDUATION, PRINCIPLE OF. The principle which makes an existing being to be an individual, so that its nature or essence is incommunicable to others and is restricted to this one.

INDIVIDUATION, RELATIVE, PRINCIPLE OF. The principle which determines the possibility of having a number of individuals of the same species.

MANICHEISM. A theory, originating with Manes, which maintained that God is the supreme Principle of Good and matter the supreme Principle of Evil.

MATTER. See Cause, Material.

MECHANISM. The theory which maintains that the ultimate constituent particles of matter are homogeneous in character, actuated by purely mechanical forces which produce only local movement.

METAPHYSICS. The science of the ultimate principles and properties of real beings.

MOTION, LOCAL. The transition of a thing from one place to another.

MOTUS. Any activity involving the transition from potency to act in a corporeal being through successive stages, i.e., a successive change in a body. The act of a being in potency while still in potency.

MOVEMENT. See Motus.

NATURALISM. The theory of Aristotle and the scholastics, that beings possess a 'nature,' in virtue of which they are specifically distinct substances with specific properties and activities.

NATURE. The essence of a being considered as the ultimate principle of its operations.

NOTHING. The absence of being.

NOTHING, ABSOLUTE. The total absence of being in every conceivable form.

NOTHING, NEGATIVE. The mere absence of some kind of being in a thing.

NOTHING, PRIVATIVE. The absence of some kind of being in a thing that is fit to have it and normally ought to have it.

NOTHING, RELATIVE. The absence of a definite kind of being.

OCCASION. A circumstance or combination of circumstances which affords an opportunity for an efficient cause to act.

ONENESS. That attribute of a being in virtue of which it is undivided in itself (and divided from every other being).

ONTOLOGY. The science of being in its most general aspects.

PASSION (REACTION). The reception of an effect from another.

PERSON. An intellectual hypostasis, i.e., an individual, complete, subsistent, intellectual substance.

PESSIMISM. The philosophic theory which maintains that evil predominates over good, because the world at large is essentially bad.

PHILOSOPHY. The science of things in their ultimate reasons, causes, and principles, acquired by the aid of human reason alone.

POSSIBILITY. Objective potency, or the capacity or aptitude of a being for existence.

POSSIBILITY, ABSOLUTE. See Possibility, Intrinsic.

POSSIBILITY, EXTRINSIC. The capacity or aptitude of a being for existence in virtue of the power of an efficient cause capable of producing it.

POSSIBILITY, INTRINSIC. The capacity or aptitude of a being for existence, due to the compatibility or non-contradiction of its constitutive elements.

POSSIBILITY, LOGICAL. See Possibility, Intrinsic.

POSSIBILITY, METAPHYSICAL. See Possibility, Intrinsic.

POSSIBILITY, MORAL. The possibility of free agents to do something without grave difficulty.

POSSIBILITY, PHYSICAL. The possibility due to the powers of a thing acting according to the laws of nature.

POSSIBILITY, RELATIVE. See Possibility, Extrinsic.

POSTURE. A disposition of parts among themselves in the sense of 'attitude'; immanent or intransitive action expressed by an intransitive verb.

POTENCY. The capacity or aptitude for something.

POTENCY, OBJECTIVE. The capacity of a non-existent being for existence.

POTENCY, OPERATIVE SUBJECTIVE. The capacity for doing something.

POTENCY, REAL. See Potency, Subjective.

POTENCY, RECEPTIVE SUBJECTIVE. The capacity for receiving an act.

POTENCY, SUBJECTIVE. The capacity of something existing for an act.

PRECISION. A process in which the mind fixes its attention upon one or the other characteristic of a thing or upon one element common to many things, excluding others which are joined to it in the real order.

PRECISION, FORMAL. A type of abstraction or precision in which the ideas drawn out by the abstractive process are only subjectively different, i.e., these ideas mutually include each other implicitly, though they do not expressly mention each other.

PRECISION, MATERIAL. A type of abstraction or precision in which the ideas drawn out by the abstractive process are objectively different, i.e., these ideas have a different comprehension or thought-content, so that the one does not necessarily include the other.

PRECISION, OBJECTIVE. See Precision, Material.

PRECISION, SUBJECTIVE. See Precision, Formal.

PREDICAMENT. An ultimate and supreme mode of being; a category.

PREMOTION, PHYSICAL. An antecedent physical influence (*praemotio physica*) which, according to Thomists, is required in order that the faculty of a creature can pass from potentiality to actuality.

PRINCIPLE. That from which something proceeds in any manner whatever.

PRINCIPLE OF CAUSALITY. See Causality, Principle of.

PRINCIPLE OF CHANGE. See Change, Principle of.

PRINCIPLE OF CONTRADICTION. See Contradiction, Principle of.

PRINCIPLE OF EXCLUDED MIDDLE. See Excluded Middle, Principle of.

PRINCIPLE OF IDENTITY. See Identity, Principle of.

PRINCIPLE OF SUFFICIENT REASON. See Sufficient Reason, Principle of.

PRINCIPLES, FIRST. See Principles, Supreme.

PRINCIPLES, SUPREME, OF BEING. Those highest principles which are immediately derived from the concept of 'being.'

PROPERTIES, TRANSCENDENTAL. The supreme modes or attributes necessarily connected with every being, which are different phases of the same fundamental being, but are not explicitly contained in its concept as such.

PROPERTY. The act or actuality perfecting and determining an essence in such a manner that the entity it gives to the being flows necessarily from its nature, without being strictly essential. PURPOSE. See End.

QUALITY. An absolute accident completing and determining a substance in its being and in its operations.

QUALITY, AFFECTIVE. A relatively permanent quality which produces, or results from, some accidental sensible alteration.

QUANTITY. An attribute of the material (determinable) element in a being.

QUIDDITY. The 'whatness' or essence of a being.

REACTION (PASSION). The reception of an action on the part of the recipient.

RELATION. It is the bearing (reference, respect, attitude, ordination) of one thing to something else.

RELATION, ACCIDENTAL (CATEGORICAL, PREDICAMENTAL). A relation based on an accident as its foundation.

RELATION, CATEGORICAL. See Relation, Accidental.

RELATION, ESSENTIAL (TRANSCENDENTAL). A relation in which the very essence of one thing has a bearing toward something.

RELATION, EXTREMES OF. The subject and term of a relation.

RELATION, FOUNDATION OF. The reason why one thing is related to another.

RELATION, LOGICAL. A relation made solely by the mind and placed by the mind between entities.

RELATION, MUTUAL. A relation whose foundation is real or logical in both extremes.

RELATION, MUTUAL, ASYMMETRICAL. A relation in which the foundation in both extremes is of a different

nature or degree.

RELATION, MUTUAL, SYMMETRICAL. A relation in which the foundation in both extremes is of the same nature and degree.

RELATION, NON-MUTUAL. A relation whose foundation is real or logical in one of the extremes only.

RELATION, PREDICAMENTAL. See Relation, Accidental.

RELATION, REAL. A relation which exists between things, independent of the mind and its thinking.

RELATION, TRANSCENDENTAL. See Relation, Essential.

SUBSISTENCE. That mode of existence in virtue of which a thing is self-contained and autonomous (*sui juris*) in its operations.

SUBSTANCE. A being whose nature it is to exist in and for itself and not in another as in a subject.

SUBSTANCE, COMPLETE. A substance whose nature demands no further union with a substantial co-principle.

SUBSTANCE, COMPOSITE. A substance consisting of incomplete substantial parts, entitatively distinct among themselves, in such a manner that their union results in a single, unified nature.

SUBSTANCE, INCOMPLETE. A substance whose nature demands that it be conjoined with some other substantial co-principle.

SUBSTANCE, PRIMARY. Any individual, concrete substantial being.

SUBSTANCE, SECONDARY. Any generic or specific substance.

SUBSTANCE, SIMPLE. A substance which does not consist of substantial parts which are entitatively distinct among themselves.

SUFFICIENT REASON, PRINCIPLE OF. The principle which states that everything without exception must have an adequate reason or ground for its being and existence, even if no production be involved.

SUPPOSITUM. See Hypostasis.

TELEOLOGY. The tendency of efficient causes to realize definite results through their action.

TERM, ANALOGOUS. A term applied to unlike things, partly for the same and partly for a different reason.

TERM, EQUIVOCAL. A term which is used of totally diverse things, so that it has entirely different meanings.

TERM, UNIVOCAL. A term which designates a number of things in an identical sense.

TERMINUS A QUO. The starting-point from which something proceeds.

TERMINUS AD QUEM. The goal or ending-point toward which something proceeds.

THOMISM. One of the schools of scholastic philosophy.

TRANSCENDENTAL. Something which goes beyond all ordinary classifications and categories of being. TRUTH. The conformity (agreement) between intellect and thing.

TRUTH, LOGICAL. The agreement of the intellect with the thing.

TRUTH, MENTAL. See Truth, Logical.

TRUTH, METAPHYSICAL. See Truth, Ontological.

TRUTH, MORAL. The agreement of speech with thought.

TRUTH, OBJECTIVE. See Truth, Ontological.

TRUTH, ONTOLOGICAL (METAPHYSICAL, OBJECTIVE).
The agreement of a being with the intellect.

UNITY. That mode or attribute of a being in virtue of which a being is undivided in itself (and divided from every other being).

UNITY, LOGICAL. The indivision of a universal idea (class) considered as a whole of which the inferiors are the parts.

UNITY, MATHEMATICAL. See Unity, Predicamental.

UNITY, NUMERICAL. See Unity, Predicamental.

UNITY OF COMPOSITION. The unity of a being in such a manner that it is a whole not actually divided into the real parts of which it consists.

UNITY OF SIMPLICITY. The unity of a thing in such a manner that it does not consist of any parts into which it could be divided.

UNITY, PREDICAMENTAL (MATHEMATICAL, NUMERICAL). A unit considered as a standard for measuring mathematical or numerical quantity.

UNITY, REAL. The indivision of a thing in its entity.

VALUE. That which is perfect or perfective.

WHEN. Situation in time.

WHERE. Situation in space.

ZOROASTRIANISM. An oriental theory, originating with Zoroaster (or Zarathustra), which maintains that the forces

of good and evil are waging a constant battle for supremacy. Ahura-mazda (Ormuzd) is the supreme Principle of Good, and Anra-mainyu (Ahriman) is the supreme Principle of Evil.

AUTHOR'S PREFACE

COSMOLOGY is a fascinating and important department of philosophy. Its very subject matter, namely, the corporeal universe in its ultimate constitution, is a challenge to the truth-seeking mind of the student.

The phenomenal success of the physical sciences in penetrating into the interior of the atom and its structure has revolutionized our knowledge of the material universe. Much of the mystery surrounding the elements and their properties has been dispelled. Scientists, since the turn of the century, have furnished data which are indispensable to the cosmologist. In no other department is the philosopher so dependent on the findings of science for the solution of his problems.

The student should have an elementary knowledge of physics and chemistry as a preparation for this course. Most teachers of cosmology, however, experience the difficulty that the acquaintance of their students with 'nuclear' physics and chemistry is too fragmentary to be of much value. The author, therefore, has deemed it advisable to devote the first part of the book to a summary of the main facts pertinent to the physical constitution of bodies.

This information should assist the student in passing judgment on the essential constitution of bodies — one of the great cosmological problems which has confronted the thinkers of all ages.

In scholastic circles the essential constitution of bodies is still treated in the light of the theory of hylomorphism. There exists, however, a theory among scholastics of the present day which deviates from this traditional doctrine. It is the theory of hylosystemism. This theory is expounded in a special chapter, so that the student may become familiar with this newest view. As for the style of the book, the author has followed the same method of treatment as in his other textbooks, *The Science of Correct Thinking*, *Reality and the Mind*, and *The Domain of Being*. He has endeavored to illustrate his material with copious examples and explanations, in language which is relatively simple and nontechnical. The summaries of the chapters and the glossary of terms at the end of the book should be of considerable help to the student in memorizing the salient features of the matter discussed in the body of the text.

It is hoped that the student, through the study of cosmology, will manage to achieve a broad synthesis of science and philosophy and thereby arrive at a deeper understanding and appreciation of the world in which he lives.

January 1, 1941

PART I

**THE PHYSICAL CONSTITUTION
OF BODIES**

Chapter 1

COSMOLOGY

MAN IS AN INQUISITIVE BEING. POSSESSING AN INTELLECT AND endowed with an insatiable desire for knowledge, he endeavors unceasingly to unravel the mysteries which surround him. Visible, physical nature, with its manifold forces and phenomena, has always held an irresistible fascination for his mind. The struggle for existence sharpened his wits and made him seek ways and means to turn the forces of nature to his own advantage. Gradually he accumulated a large store of useful, but more or less unrelated, information concerning physical beings, their properties and activities. In the course of time this led to the development of science and philosophy.

PRESCIENTIFIC KNOWLEDGE

Knowledge comes from *experience*. We see, hear, feel, taste, smell; this is sense perception, because by means of these sensations we 'perceive' color, sound, heat, flavor, odor, etc. We are conscious of these perceptions from the days of our childhood, and we experience them as long as we live. We recognize objects by means of the continued

presence of one or more of these sensible qualities. An orange is predominantly yellow in color, more or less spherical in shape, somewhat rough to the touch, sweet to the taste, and of a definite, fragrant odor. Ice is transparent, cold, practically tasteless and odorless, and very hard.

All men (a few philosophers excepted) are convinced that the *objects* which we recognize by these sensible qualities are *objectively real*. When we call them 'objectively real,' we mean that they exist, not in our imagination alone, but as 'things,' just as we ourselves exist. They are beings with an existence of their own which is independent of our thought. They are outside our mind in space and time, and would remain there even if our mind ceased to exist. These objects, like ourselves, are parts of the physical world.

With normal sense organs and with a little attention, all men are capable of distinguishing the ordinary objects encountered in the experience of their daily observations: wood, water, fire, stones, buildings, hills, clouds, trees, animals, men, etc. Many of these objects are perceived to have a definite *activity*: wood burns, water flows, fire warms, clouds move, trees grow, animals and men eat and drink. Under ordinary circumstances most objects have *properties* which are *characteristic of their type*; for example, gold is yellow and malleable, air is light and gaseous, a diamond is hard and brilliant. Other properties are common to all sensible things: they occupy space in three dimensions and persist in time.

On the basis of such properties and activities, man has always arranged the objects of nature in a broad *system of classes*. The *two* main divisions are: living and nonliving. The chief subdivisions of living beings are: plants, animals, men. And the chief subdivisions of nonliving beings are: solids, liquids, and gases. These divisions and classifications are obvious, and are the result of man's natural tendency to generalize his experiences and to systematize his observations. Besides this division into broader classes, one finds a grouping of things into limited classes. This is evidenced by the class names found in every language: for instance, 'birds,' 'dogs,' 'trees,' 'hands,' 'heads,' 'stones,' 'rivers,' 'flowers,' 'mountains,' 'valleys,' etc. Such classifications belong to all men, irrespective of time, place, and culture.

Through his knowledge of individual objects man, even though primitive and savage, comes to know the various *relationships* which exist between these objects. Things are discovered to be, not in complete isolation, but in definite relation one to another; they are not a jumble and chaos of single beings, but an interrelated group of beings, arranged in a system of mutual dependence: they form together a real *world*. The untrained mind of primitive man may have a world picture which is crude and inaccurate; nevertheless, the fact that he has such a conception is undenied and undeniable.

The ordinary man accepts the objects and phenomena of the physical world without question as to their reality; and he accepts them as he perceives them through his senses. To him *things actually are as they appear*. The rose is truly

red and the lemon yellow, in the meaning that the color actually resides in these objects without reference to any eye that sees them. Ice is cold and a flame is hot; and the qualities of heat and cold are objectively present in the things themselves. The same is true of all other qualities perceived by the senses: they are as objectively real, independent of the senses and of the mind of man, as the objects themselves are real. To the ordinary man a block of metal, say of gold or lead or iron, is actually a continuous substance, and not an aggregate of discrete, separated particles. If a coin and a feather are dropped at the same moment from a second-story window, the coin will reach the ground first, and he is convinced that heavier objects fall faster than those of lighter weight. He judges things to be in reality as they appear to be to his senses.

Of course, even primitive man is aware of the fact that appearances often deceive. Things appear different in a fog or in the twilight from what they do in the bright sunlight. If he is ill, the flavor and odor of many familiar objects seem to have undergone a change. When he plunges a half-frozen hand into tepid water, the water feels uncomfortably hot. A straight stick appears bent or broken, when partly submerged in water. And so with a thousand other phenomena. Such facts, however, are not enough to shake his spontaneous conviction that his senses can be trusted to represent physical reality as it actually exists in nature. Apparent illusions are explained by the lack of proper conditions.

That normal sense perception suffices for man to orientate himself in this physical world according to the

requirements of his ordinary life, is evident from every individual's own experience. That the knowledge of things thus acquired is rather gross and superficial, is also evident. Solely through their own powers the senses can tell us little about very minute and very distant bodies. The field of perception is limited in extent, and the powers of perception are decidedly restricted. Of the inner nature and constitution of physical bodies the intellect alone can judge, and in order to judge of these matters with any degree of certainty or probability, the intellect must rely on the data furnished by sense perception. Since, however, the senses are affected by objects and occurrences only in their grosser external appearances, the intellect frequently lacks the data necessary for a correct and adequate interpretation of the phenomena of nature. As long as the effectiveness of the senses was not increased by means of special instruments and methods, man's ordinary knowledge could not become truly scientific to any great extent.

Such knowledge is mostly prescientific, and by *prescientific knowledge* we understand the knowledge of physical objects and phenomena which is acquired through ordinary sense perception, without the aid of special experimental methods and precision instruments which enable the intellect to formulate well-grounded interpretations concerning the constitution of these objects and the causes which produce these phenomena. Prescientific knowledge is rather meager in content and, in a large measure, inexact and incorrect.

SCIENTIFIC KNOWLEDGE

Science endeavors to give a more precise and comprehensive explanation of the objects and occurrences of nature than is possible through ordinary experience and observation. *Science* is the orderly knowledge of things *in their causes*. In order to achieve this type of knowledge it makes use of more refined methods of observation and experimentation. The sense organs of the scientist are, of course, the same as those of any other human being. By means of various devices and instruments, however, their effective range of perception is increased to a remarkable degree.

Consider the microscope. A drop of water taken from a brook seems, to the unaided eye, to consist of a perfectly clear fluid in which there are no foreign bodies present. When viewed under the microscope, however, the drop is observed to swarm with minute living beings. The microscope thus enables the scientist to obtain much more accurate knowledge about things than plain vision could ever reveal. And there is the telescope. Objects such as the stars, that are far beyond the reach of man's unaided vision, are brought considerably nearer (apparently, of course), so that he can subject them to a closer and more exhaustive scrutiny; facts are thus revealed to him which would otherwise remain unknown. The fine lines of the spectroscope disclose to the trained observer the presence of elements in a body which even the most powerful microscopes and telescopes do not detect. Heat, light,

magnetism, and electricity can be measured in infinitesimal quantities by means of scientific apparatus.

By using such instruments, the scientist eliminates to a great extent the uncertainties involved in the subjective differences of sense organs of the individual observers. The result is a more *objective knowledge* of physical objects and forces. A photographic plate and an electroscope, for example, are not influenced by the emotions, diseases, prejudices, and pet theories of the observer; they record the objective factors at work in nature, irrespective of the wishes or hopes of the scientist using them. The instruments of science thus give us a deeper and more extensive knowledge of individual physical phenomena, and also a more objective picture of the world at large. In this manner *factual observation* is greatly enhanced, far beyond the wildest dreams of the ancients.

Science is the knowledge of things in their causes, and *experimentation* has proved to be a powerful method of discovering and investigating the causes at work in physical phenomena. An experiment is the observation of phenomena under selected and controlled conditions. The intermingling of causes and effects in nature is extremely baffling to the unscientific observer. There is a constant interplay of unseen forces in physical occurrences, and the detection of the actual causes is a difficult task. Unknown forces may always be at work in a given event, and a selective arrangement of conditions will more readily disclose the presence or absence of such causes. At the same time irrelevant facts, which might obscure the issues, are thereby eliminated, making the results more certain. By

shifting the various factors which come into consideration as possible causes and arranging them in varied experiments, the possible causes will be gradually reduced in number, until one single cause is left to account for the phenomenon in question.

From facts the scientist proceeds to the *interpretation of facts*. The first requisite for scientific knowledge is a relatively complete and accurate description of the objects, their properties and activities. This, however, is merely the groundwork of science. Science attempts to understand the physical structure and constitution of bodies and endeavors to explain the phenomena resulting from their causal activities. Common-sense explanations are all too often misleading and inaccurate, if not altogether erroneous. Hence, the scientist must use his imagination and intellect in seeking an interpretation of the facts which will give a true and full account of the phenomena under consideration.

As a rule, the problems are intricate and obscure, and a complete solution is at first unavailable. The scientist then has recourse to *hypothesis* and *verification*. An hypothesis is the provisional explanation of a phenomenon, based on probable arguments, until verified (or disproved) by subsequent evidence. An hypothesis is more than a mere guess or opinion; it is a justifiable assumption which lends itself to a tentative explanation of a fact or law, so that it can be used as a guiding norm in making observations and experiments. A scientific hypothesis must cover all relevant facts, must be simple and consistent, and must lend itself to making reasonable predictions which can later be verified.

Benjamin Franklin, for instance, held the hypothesis that lightning was of the character of an electric discharge; he verified this hypothesis by means of his famous kite experiment. Louis Pasteur, from the fact that the souring of milk was due to a germ, conceived the hypothesis that all fermentation, decomposition, and contagious diseases were caused by microbes; subsequent experiments verified his assumption.

From the above it should be clear that the general method of reasoning employed by natural science is that of induction. *Induction* is the process of reasoning in which we conclude from individual cases to the existence of general laws or principles. It would be an error, however, to judge from this that induction is the sole method of scientific investigation. Once a law of nature is duly verified and established, it can be used as a general principle or truth applicable to individual cases. We are then justified in concluding from the truth of the law to the truth of the individual cases which fall under this law. This method of inference is *deduction*, or the process of reasoning in which we conclude from a general law or principle to a particular instance falling under the general law or principle. Both methods of reasoning are employed by scientists in their investigation of nature.

Natural science rests upon certain *fundamental presuppositions*. It cannot prove everything; it must take some things for granted. One of these presuppositions is the *existence of the physical world*. Obviously, the scientist could never investigate the physical world and the objects and phenomena present therein, if he were not convinced

that the physical world actually exists. This existence is simply accepted as given. A second presupposition of science is the knowability of the physical world. It would be useless for the scientist to begin to examine nature, if he held the opinion that man cannot acquire a true and certain knowledge of it, or that physical objects cannot manifest themselves to man. Another, equally important presupposition is the essential *trustworthiness of man's powers of knowledge*. The true scientist cannot be a skeptic. To maintain that man's faculties of sense perception or reasoning are radically unreliable or even doubtfully reliable in arriving at truth and certainty, would vitiate his research work from the very start; he could never be certain that his conclusions are true. A fourth presupposition is the *uniformity of nature*. If nature were not accepted by the scientific investigator as orderly, constant, and governed by uniform laws throughout the universe at all times, the facts which he establishes today might be reversed tomorrow. If this possibility were conceded, there could be no science of nature, because science treats of general laws and principles, and not of individual objects and occurrences. Lastly, the validity of the *Principle of Causality*, namely, that everything which happens must have a producing cause to account for its being and existence, is a presupposition of natural science. Why look for the causes of phenomena, if the latter can occur without any cause? It is precisely through their causes that the scientist attempts to explain the existence and nature of the phenomena. Science would be futile and illusory, if this principle were invalid. These are the main

presuppositions of science, and they must be accepted by the scientist before he begins his study of nature.

Is the scientist justified in accepting these presuppositions without first establishing their validity? As a scientist, yes. It is the duty of the *philosopher* to establish their reasonableness, and that need not concern us at present, because the proof of the validity of these principles and postulates has been given elsewhere.¹

What is the *purpose* of natural science? It examines individual objects by means of experience and experiment, in order to discover that which is typical or representative of them all as a class. It seeks generalizations and laws, causal relations of a universal character, the elements which explain the constitution of the objects or bodies existing in the physical universe. In other words, the natural sciences are the sciences which seek, by means of experimental methods, to attain certain knowledge about the properties, activities, and constitution of corporeal substances through their proximate causes. Such knowledge is *scientific knowledge*.

PHILOSOPHIC KNOWLEDGE

Philosophy attempts to give us a knowledge of things which is ultimate in their line of being. *Philosophy* is defined as the *science of beings in their ultimate reasons, causes, and principles, acquired by the aid of human reason alone*. It is a 'science'; that is to say, it is certain knowledge derived from reasoned demonstrations of causes and reduced to a system. It is a science of beings,' of all things which can be

reached by the human mind directly or indirectly — man, the world, God. It is the science of beings ‘in their ultimate reasons, causes, and principles.’ A ‘reason’ is that by means of which a thing is known and can be understood; a ‘cause’ is that which contributes in some positive manner in the production of a thing; a ‘principle’ is that from which something proceeds. Philosophy is not content with the proximate causes of things, but searches for an understanding and explanation of things in their ‘ultimate,’ most fundamental reasons, causes, and principles. Finally, philosophy is the science of beings in their ultimate reasons, causes, and principles, ‘acquired by the aid of human reason alone.’ It does not seek its information from mystical experience or divine revelation, but intends to solve its problems solely through the use of man’s native powers of knowledge. The material object, or general subject matter, of philosophy is, therefore, all being in the widest meaning of the term; its formal object, or special viewpoint, is all being considered under the aspect of its ultimate reasons, causes, and principles.

The human mind is not even satisfied with the findings of science. Science discloses the ‘proximate’ causes which produce the mysterious phenomena of the physical world. Philosophy would fain uncover the ultimate causes of things. It accepts the discoveries of science when they are reasonably established; but there still are deeper problems behind the problems of science, and these philosophy attempts to solve. All experimental sciences deal with bodies, substances, quantities, energies, physical and chemical changes, space and time, matter and mass, motion

and force, and similar entities. All these things flow from the inner nature of material bodies and receive their ultimate explanation in this inner nature and essence. The problem of essences lies outside the limits of sciences and belongs to the province of philosophy.

While the experimental sciences all treat of the visible universe, each has its own particular field. Physics treats especially of the transmission and transformation of energy in its various forms. Chemistry deals mainly with the properties, compositions, and changes of elements and compounds. Biology is interested in vital organs and functions, and in their development. Geology seeks to trace the past history of the earth. Astronomy studies the universe of the stars. In many ways these sciences develop independently, and at times the findings and conclusions of one science are more or less at variance with those of another. The universe, however, is one, consisting of the same elements and laws throughout. Philosophy seizes upon the factors and principles common to all the sciences and seeks to propound a world picture which will bring these scattered and partly disagreeing fragments of knowledge into a higher synthesis. After all, there can be no real division in knowledge, because there is no real division in nature; nature being a complete synthesis, our knowledge of the world must end in a similar synthesis.

Philosophy views all things in their most general and most fundamental aspects. The physical world consists of an immense variety of bodies, organic and inorganic, elemental and compound. They all, however, agree in this fundamental feature, that they are *material bodies*. And

while certain types of bodies have properties and activities which are characteristic of the types, all types have definite properties and activities which are *common* to all types, because they pertain to bodies as such. The particular sciences are concerned with the special types of bodies, but philosophy deals only with bodies as such and with their most general properties and activities.

Now, that part of philosophy which treats of the material world in this manner is called the *philosophy of nature*.

COSMOLOGY

Cosmology (Gr., *κόσμος* world, and *λόγος*, knowledge or science), as the etymology of the term indicates, is 'the science of the world.' Considered from this standpoint, cosmology deals philosophically with the entire material universe, including inorganic substances, plants, animals, and man; as such, its meaning coincides with 'philosophy of nature.' The term 'cosmology' originated with the philosopher Christian von Wolff, in 1730. Before his time this part of philosophy was designated 'philosophy of nature,' 'natural philosophy,' or simply 'physics'; and the term comprised the study of the whole universe in its philosophic aspects. That is, however, no longer the case. The field has been divided. Man, with his vegetative, sentient, and intellectual life, is the subject matter of psychology. For a similar reason, plants and animals, since they have vegetative, or sentient and vegetative life, are bracketed with man as organic beings and are treated in psychology. Viewed in this manner, plants, animals, and man

are excluded from the subject matter of cosmology. Other cosmologists, however, insist that organic beings, since they belong to the material universe, must be included in the study of cosmology.

Cosmology, as accepted here, is defined as the science of the corporeal universe in its ultimate reasons, causes, and principles. Primarily, though not exclusively, we will direct our attention to inorganic nature, in the sense of individual bodies and in the sense of the universe as the assemblage of all bodies.

The universe is enormously vast in extent, and it consists of innumerable *individual bodies*. The star is a body, and so is the atom; the chemical compound is a body, and so is the chemically simple element. All agree in this that they are '*bodies*,' corporeal beings. It will be one of the chief problems of the cosmologist to answer the question: What is it that all bodies have in common? Bodies, however, are also specifically different among themselves; one element, for example, appears to be totally distinct from another element. This fact, if true, raises another question: What is it that makes bodies specifically different? And since elements are apparently united into compounds and compounds dissolved into elements, a further question arises: Is there a substantial change among bodies, and if so, how is this change effected? The result of all this then leads to the question of ultimate importance: What is the inner constitution of all bodies as bodies?

All bodies, taken together, form a totality which we call the *universe*. Here, too, a number of important questions force themselves upon our mind for a possible solution.

Such questions are: Is the universe a cosmos or only a conglomeration of unrelated bodies? What is the origin of the universe? How did it develop? Is it infinite? Will it last forever or come to an end? What is its purpose, or has it no purpose?

These are some of the problems which confront the cosmologist. If he can find an answer to even some of these questions, he will have performed a valuable service to the student of nature.

COSMOLOGY AND SCIENCE

In the course of the history of philosophy, many types of cosmological theories and systems have been advanced as comprehensive solutions to the problems just mentioned. In general, up to within a century and a half ago, philosophy and science were one; the philosopher was the scientist, and the scientist was the philosopher. In modern times, however, the experimental sciences have blazed a trail of their own, independent of philosophy. Empirical knowledge, that gained by instrumentally refined observation and experimentation, became the goal of the sciences, content with discovering the proximate causes and principles which account for the phenomena of the physical world. Each science restricts itself to its own particular field and is no longer concerned with the more fundamental problems involved.

Cosmology and physical science agree in their general or 'material' object, but differ in their specific or 'formal' object. The *material object* for both is the *corporeal*

universe. The *formal object* for physical science is the 'proximate' causes and principles which explain the phenomena of the material world, while the *formal object* for cosmology is the *ultimate* reasons, causes, and principles of corporeal beings in general and of the universe at large. Thus, although science and cosmology have much in common, they are in no way identified or identifiable, because each treats the world from a different viewpoint. Cosmology begins where science ends.

Cosmology and science are not in opposition to each other. Science has accumulated an immense store of factual information about physical nature, and the data furnished by it are of inestimable importance to cosmology. Cosmology depends almost entirely upon science for the materials of its investigation. It is because of a lack of precise scientific information that so many cosmological theories and systems of bygone days must be discarded as inadequate or erroneous. Since the knowledge of corporeal beings, as acquired through science, is so exact and comprehensive, the task of cosmology has become appreciably easier. True science will always be the ally of cosmology, while cosmology is the complement of science.

METHOD AND DIVISION

In the past philosophers were compelled to build their theories and systems upon a foundation of knowledge which was hopelessly incapable of supporting the large structure based upon it. This knowledge was prescientific, not scientific, and it was very meager in content. Even the

geniuses of *Aristotle, St. Albert, and St. Thomas Aquinas* could not overcome the handicap of unscientific information. They did the best they could with the material at hand, but their best was frequently not good enough. They must be admired for their gigantic efforts rather than for their actual achievements, when it is a question of the philosophy of nature. Their knowledge was encyclopedic in character, but much of it, due to the lack of scientific method, was untrue.

They knew and recognized the value of the inductive method of reasoning from individual facts to universal principles and laws; but they were forced by circumstance to attempt a solution of their cosmological problems by having recourse to deduction, perhaps more than they desired, by reasoning from general principles and axioms to the individual facts. Arguing deductively, however, in this manner regarding facts of the material order is always a dangerous procedure, unless the universal principle has first been established by means of sound inductive reasoning. When the premises are of doubtful truth, the conclusions will also be uncertain.

Fortunately, that condition of affairs has changed. Science, through its discoveries, has been able to supply the cosmologist with abundant accurate information. The very success of experimental science in the last century and a half is ample proof that the inductive method of science was the proper approach to the mysteries of the physical world. No cosmologist can afford to ignore either the material furnished by natural science or the inductive method which has been its chief instrument of investigation.

Science and cosmology deal with the same object, the material universe; it should therefore also be advantageous for both to use the same fundamental method of investigation, namely, *induction*.

Induction is not the sole instrument of cosmological research. There are certain supreme principles of thought and of being — metaphysical, ontological principles — which apply to all systems of thought and of being and are valid at all times and in all conditions. Scientific theories which run counter to them cannot be valid and true, because the laws of thought and of being are in essential harmony. Hence, scientific and cosmological theories can and must be checked by their agreement or disagreement with these supreme principles. It is a legitimate procedure to conclude deductively from the metaphysical principle to the individual case or theory. *Deduction*, therefore, must not be overlooked as a method of investigation in cosmology. As a matter of fact, both induction and deduction have their proper places in the search for truth.

Generally speaking, it has been the fault of philosophers in the past to rely more on the simpler method of deduction than on the slower and more painstaking method of induction. In cosmology this might, and in all probability would, be fatal to the acquisition of knowledge and truth. We will, therefore, follow closely in the footsteps of science and borrow largely from its fund of information. Science is not infallible, of course, nor are all its conclusions and theories free from error or doubt; and science is still learning new facts. But the safest plan for the cosmologist is to accept his material from the hands of the scientist.

The *division* of the book is simple. The student is expected to have a general knowledge of the natural sciences. Since, however, not everything in these sciences is pertinent to the study pursued in cosmology, the first part will contain a summary of the relevant scientific facts and factors concerning the *physical constitution of bodies*. The second part will treat of the *general properties* of bodies. The third part will seek to solve the problem of the *essential constitution* of bodies. The fourth part will then consider the assemblage of bodies as a *universe*. In this manner it is hoped that the student will become fairly well acquainted with the many problems which the cosmologist seeks to solve.

SUMMARY OF CHAPTER I

Science and philosophy are the outcome of man's insatiable desire for knowledge.

1. *Knowledge* results from experience. To the ordinary, unscientific man things actually are as they appear. Such knowledge is mostly *prescientific*, i.e., a knowledge of physical objects and phenomena which is acquired through ordinary sense perception, without the aid of special experimental methods and precision instruments which enable the intellect to formulate well-grounded interpretations concerning the constitution of these bodies and the causes which produce these phenomena.

2. *Scientific* knowledge is the knowledge of things in their causes. To acquire it, the natural sciences make use of refined methods of observation and experimentation. Such knowledge is more exact and objective. *Induction* is the general process of reasoning employed, though deduction also plays a prominent part in scientific research.

3. *Philosophy* is the *science of beings in their ultimate reasons, causes, and principles*, acquired by the aid of human reason alone. Philosophy seizes upon the factors and principles common to all science and seeks to propound a world picture which will bring the scattered and partly disagreeing fragments of knowledge into a higher synthesis.

4. *Cosmology* is the *science of the corporeal universe in its ultimate reasons, causes, and principles*. Since life in its various phases is the subject matter of psychology, we will

restrict the study of cosmology mainly to inorganic nature, in the sense of individual bodies and of the universe as the assemblage of all bodies.

5. *Cosmology and Science*. The material object of both is the corporeal universe. Their formal object is different: science seeks the 'proximate' causes and principles which explain the phenomena of the material world; for cosmology the formal object is the 'ultimate' reasons, causes, and principles of corporeal beings in general and of the universe at large.

6. *Method and Division*. To a very great extent the inductive method of science must be employed, and cosmology must borrow much of its material from the experimental sciences.

On the other hand, scientific and cosmological theories must be checked deductively by their agreement or disagreement with the supreme principles of thought and being.

The *first* part of the book treats of the physical constitution of bodies; the second, of the general properties of bodies; the third, of the essential constitution of bodies; the fourth, of the universe at large.

Chapter 2

THE ELEMENTS

THAT THE PHILOSOPHER HAS A BROADER AND DEEPER knowledge of the properties, activities, and the physical constitution of material substances, is to a great measure due to the painstaking researches of the physicists and chemists. While the scientists as such do not, or at least should not, delve into philosophical problems, many of their findings contain important philosophical implications. The philosopher must take these implications into account in his own study of nature and of natural bodies. He may disagree with some of the *theories* and *conclusions* of scientists, but he must accept the facts discovered by them. Any philosophical theory or hypothesis which is in disagreement with such facts must be adjudged erroneous, because nature does not contradict itself.

To proceed, then, in an orderly and logical fashion, it will be necessary to find out what the physicists and chemists can tell us of the fundamental properties, activities, and structures present in nature, in so far as they are pertinent to the subject matter of cosmology. Not everything need or will be considered, because cosmology does not treat of chemistry and physics directly.

MATTER AND ENERGY

The chemists and physicists define *matter* as anything which occupies space. This is a scientific, not a philosophical, definition of matter. 'Space' here means the three dimensions of length, width, and depth. Anything that exists in these three dimensions is said to 'occupy space.' In order, however, that any object exist in three dimensions, it must possess length, width, and depth within itself; it must be a three-dimensional object in order that it can occupy three-dimensional space. Matter, then, is a three-dimensional object, and this physical definition can be accepted provisionally as a starting point of discussion.

It is customary to distinguish between *ponderable* and *imponderable* matter. Ponderable matter is any three-dimensional object which has weight, while imponderable matter has no weight. 'Weight' is the measure of the attractive force of the earth for an object in, on, or at a distance from it. It varies with the distance of the object from the center of the earth. All are familiar with the phenomenon of weight. A cubic foot of lead weighs more than a cubic foot of aluminum, and a piece of wood weighs less than a piece of iron of the same size and shape. An example of imponderable matter would be the aether as conceived by scientists. It is a material substance filling the pores of all ponderable matter and pervading all interstellar space of the universe.

Closely akin to the term 'matter' are the terms *material substance*, and *body*. The exact philosophical meaning of these concepts will be reserved for future examination;

here we shall explain the terms simply as currently used by scientists and philosophers. In *scientific* parlance, a 'body' is a portion of matter, and it is thereby distinguished from things like 'quantity,' 'quality,' 'energy,' 'force,' etc. Bodies are divided into two main types or classes, namely, substances and mixtures. 'Substances' are divided into elements and chemical compounds. In *philosophical* parlance, a 'substance' is any being which exists in itself and for itself, not needing any other being in which it must inhere in order to have existence. Such substances may be either spiritual, e.g., God, or material, e.g., organisms, elements, chemical compounds, mixtures, electrons, protons, etc. 'Bodies' are material substances which are individual beings with a complete identity of their own. Philosophy and science, it should be noted, do not use these terms in identical meanings. The context will show in which meaning the terms are used.

Energy is the *capacity for performing work*. In order to understand energy in the meaning of the physicist, we must know the meaning of 'work.' Work is the product of a force by the distance through which the force acts; that is to say, *work equals force times distance*. In all types of work resistance in some form must be overcome. In pulling a bag of potatoes over a cement floor, we encounter frictional resistance: by overcoming this resistance work is done. In lifting this bag of potatoes vertically from the floor, we do work against the force of the earth's attraction. Again, if the bag of potatoes rests on the floor and we set it in motion or change its velocity (disregarding friction in the process), we

do work against its inertia. In all such cases this work is measured by the formula 'force times distance traveled.'

Scientists sometimes use the terms 'energy' and 'work' as identical in meaning. Strictly speaking, however, the meanings are diverse. Energy is the *cause* of work, but not the work itself. Energy is present in a body, enabling it to do work on another body by displacing it through a certain distance. Work is done in a body when this energy becomes active; but energy may be present without being active. Hence, 'energy' and 'work' are distinct terms with different meanings. This will become clearer when we consider the two types of energy, potential and kinetic.

By *potential energy* we understand the energy which a particle, body, or system of bodies possesses in virtue of its position or configuration in reference to the *position* or *configuration* of other particles, bodies, or systems. If a rubber band is stretched, work is done on it by changing the position or configuration of its particles. During the time in which it remains in this stretched condition it is at rest; but it possesses an amount of energy equal to that of the work done upon it in stretching it. That is evidenced by the fact that, if the rubber is released, it will immediately and of itself reverse the work done on it by returning to the previous position or configuration of its particles. This energy of the rubber band, due to its position, is potential energy. It is called *potential*, because it is latent and nonactive, but is capable of *becoming* active and doing work when released. Potential energy is energy stored up in a body which is held by some constraint from passing over into motion.

By *kinetic energy* we understand the energy which a particle, body, or system of bodies possesses in virtue of its *movement*. Through their movement bodies can do work on other bodies; while doing this work, they gradually lose velocity. When a speeding bullet strikes a block of wood, it does work on the wood by overcoming its resistance and penetrating it; but in doing so, its velocity is slowed down more and more, until it eventually comes to rest. The energy of the bullet is due to its motion, and that is 'kinetic' energy (*κίνησις*, movement). The kinetic energy of a flash of lightning will shatter a tree; that of an ignited charge of dynamite will demolish a building; that of an electric generator will drive trains, illuminate cities, heat dwellings, cook food, and melt rocks. Kinetic energy is really potential energy which has become active, after the constraint, which has held the potential energy in a stored-up condition, has been removed. Energy is the active agent or cause which produces all the changes in the universe.

One form of energy can be transformed into *another*. The chemical energy of a storage battery or a dry cell is transformed into electrical energy. The electrical energy, when passing through the filament of a lamp, is transformed into light and heat. Light activates a selenium cell and sets mechanical appliances in motion. The gravity energy of falling water turns a turbine, which operates an electric generator, and is thus transformed into electrical energy. The chemical energy of exploding gasoline is transformed into the mechanical energy of the automobile motor; on its part, the mechanical energy of the automobile motor, by operating a generator, charges the battery and is

thus transformed into chemical energy; this chemical energy of the battery is transformed into electric energy; and this electrical energy is transformed into light energy and heat energy in the headlights.

ELEMENTS AND CHEMICAL COMPOUNDS

There are many ways of classifying material substance. From the standpoint of cosmology, we are interested only in the most fundamental kinds or classes. Such are *elements* and *compounds*.

In a general sense, an element is the basic type of matter into which physical bodies can be resolved and from which they originate. The question of the original element or elements of the universe agitated the minds of the earliest Greek philosophers; in fact, the attempt to find an answer to this question was the beginning of philosophy among the Greeks. *Thales* (about 620 B.C. to 546 B.C.) considered 'water' to be the ultimate principle of matter. Others took up the problem and offered other solutions. *Empedocles* (about 490 B.C. to about 430 B.C.) mentioned four elements as the ultimate constituents of all bodies and as the basis of all change, namely 'fire,' 'air,' 'water,' and 'earth.' To these four *Aristotle* (384 B.C. to 322 B.C.) added a fifth element, or *quintessence*, namely 'aether'; this he considered to be the distinctive element of all stars, while the four elements of Empedocles enter into the composition of all earthly bodies. Aristotle's teaching was accepted and upheld by intellectual men and philosophers for two thousand years. Even St. Albert the Great and St. Thomas Aquinas were

unable to improve on this list; they made it the basis of their cosmological inquiries.

The beginnings of the modern science of chemistry are found in the endeavors of the alchemists to transmute base metals into silver and gold. Alchemy had been practiced in some form or other for a thousand years or more, up to the sixteenth century. During the sixteenth century the *spagyrist*s took the place of the alchemists. Instead of searching for the 'philosopher's stone' to make noble metals, they directed their efforts toward the discovery of chemical remedies for diseases. In the course of these researches many new substances together with their compounds were discovered, among them some true elements. At the same time, a more scientific knowledge of the chemical and physical properties and activities of these substances was acquired, and this paved the way for modern science. Gradually, through the work of men like *Robert Boyle* (1627—1691), *Becher* (1635—1682), *Stahl* (1660—1734), *Priestley* (1733—1804), *Cavendish* (1731—1810), *Lavoisier* (1743—1794), *Dalton* (1766—1844), and *Berzelius* (1779—1848), a considerable number of elements became known, and chemistry emerged as a science in its own right.

An element, in a chemical sense, is any material substance which cannot be resolved by ordinary chemical means into two or more simpler substances different in nature from itself. A chemical compound is a substance composed of two or more elements chemically combined in definite proportions by weight.

It is stated in this definition that elements, to form a real compound, must be 'chemically combined.' Not every combination results in a chemical compound. Some combinations are nothing more than mixtures. A mixture is a body composed of two or more substances, each of which retains its own specific properties. A mixture has certain characteristics which distinguish it from a true compound. The combining substances in a mixture retain their original identity, so that a mixture is heterogeneous in content. Sodium bicarbonate, starch, and alum are a mixture used as baking powder. In a mixture the composition is variable; any quantity, for instance of alcohol and water, can be united. In many cases the ingredients can be separated from each other by some mechanical device, such as a centrifuge. The original energy of the ingredients is not altered in a mixture.

On the other hand, a true chemical compound is *homogeneous* throughout; it is a chemically new substance with new properties, the original elements losing their chemical identity in the process of combination. Hydrogen, for example; is a highly inflammable gas, with its melting point at -259° C. and its boiling point at -252.6° C. Oxygen is also a gas, supports combustion, with its melting point at -218° C. and its boiling point at -182.5° C. When hydrogen and oxygen unite in the process of combustion, water results. The melting point of water is 0° C., its boiling point 100° C., and it is neither inflammable nor does it support combustion. Hydrogen and oxygen are thus seen to have lost their chemical identity, changing into a new

homogeneous substance quite different from themselves, water.

Furthermore, a chemical compound cannot be reduced to the original elements except by chemical means. Since the compound is homogeneous throughout, every portion, no matter how small, has the same nature and the same properties as the entire compound. Hence, fractioning, or the division of a large amount into ever smaller portions, will never reduce it to its original ingredients. Water, for example, even when vaporized into the smallest possible particles, always remains water. An electric current, however, will separate water into its two component gases, hydrogen and oxygen, because this is a 'chemical' reaction.

Again, a compound is a combination of elements in *definite proportions of weight or volume*. 22.326 liters of hydrogen weigh 2 grams, while the same volume of chlorine, which is 35.5 times as heavy as hydrogen, weighs 71 grams. Hydrogen and chlorine will combine only in this proportion of 1 to 35.5 by weight, or — which is the same — of 1 to 1 by volume. Any excess of either element will remain unchanged in the process. The result of the combination is hydrochloric acid, a new chemical substance with new properties. 8 grams of oxygen, to take another example, will combine with 23 grams of sodium, 39 grams of potassium, 35.5 grams of chlorine, 79.9 grams of bromine, or 126.9 grams of iodine. No matter what the absolute quantities may be (whether milligrams, or kilograms, etc.), this proportion must be maintained for the elements to combine chemically and form a compound. This *law of combining weights* does not apply, as was mentioned

before, to substances united in a mixture; such substances can be mixed together in variable proportions.

Finally, the *quantity of energy* in a compound is not equal to the sum of the energies present in the elements before combination. The compound always either gains or loses energy. Every chemical change is accompanied by heat. In some cases heat is absorbed by the compound, while in other cases heat is emitted and lost. For example, hydrogen burns when combining with oxygen to form water. If 2 grams of hydrogen and 16 grams of oxygen, at standard pressure and temperature, unite at a temperature of 0° C., 68,834 calories¹ are liberated in the process. In the reaction which takes place when 65 grams of zinc are dissolved in dilute sulphuric acid, water is decomposed, 2 grams of hydrogen are evolved, and in this process 68,834 calories are absorbed. The quantity of energy in the compound is thus seen to be either smaller or larger than the sum of the energies in the ingredients. Reactions which absorb heat energy are called 'endothermic,' while those which liberate heat energy are called 'exothermic.' Like the proportion of weights, the amount of calories absorbed or liberated in the reaction is always the same for the same quantities under the same conditions.

PHYSICAL AND CHEMICAL CHANGES

Nature is an immense theater of continuous changes. No single bodies or groups of bodies are entirely free from change. Something is done to them, or they do something

to other bodies, in a continuous cycle of activity. The two main classes of changes are physical and chemical.

A *physical change* is a change in which the elements or the compounds of elements *retain their substantial identity* in the alteration. In a physical change nothing happens to the element as an element or to the compound as a compound; they remain that particular element or that particular compound before, during, and after the change is effected. A physical change, therefore, merely alters certain unessential qualities, properties, and energies, without affecting the nature of the material substance as such. A few examples will clarify the concept of physical change.

Heat applied to ice turns it to a liquid, and applied to liquid water turns it to steam; but water is not decomposed into oxygen and hydrogen in the process. Electricity flowing through a tungsten filament in an electric bulb heats it to incandescence; the filament emits heat and light, but it still remains tungsten. Iron filings placed near a magnet become magnetized and themselves act as temporary magnets; but they do not lose the nature of iron on that account. Pressure will decrease, and moderate heat increase, the volume of a gas without destroying the nature of the gas itself. A spring can be coiled, a piece of rubber stretched, a stone ground to powder, a shell shot out of a canon, a machine made to work, but these things retain their identity throughout the change. These examples show various energies and forces acting upon bodies, producing temporary physical changes which do not alter the material substances in their chemical nature.

A *chemical change* is a change in which the substance or substances *lose their identity and become new chemical substances* with new physical and chemical properties and have new energy contents. Such changes are not temporary in character but remain permanent, until another chemical change sets in. The formation of chemical compounds, as explained in the foregoing section, is the result of a chemical change. There are, however, various kinds of chemical changes. They can be arranged in four groups: chemical combination, decomposition, displacement, and double decomposition.

In a chemical *combination* elements or compounds unite to form complex substances. Magnesium in air, upon being heated to kindling temperature, bursts into flame with a blinding white light, forming the white powder of magnesium oxide. Hydrogen and oxygen combine to form water. In a chemical *decomposition* compounds are reduced to simpler compounds or to the elements. Mercuric sulphide, an ore called cinnabar, when roasted, decomposes into mercury and sulphur. By heating silver oxide, the compound is broken down into oxygen and metallic silver. In chemical *displacement* one element takes the place of another element in a compound. If zinc is put into a copper sulphate solution, a reaction occurs in which copper is replaced by zinc. So, too, in a reaction between iron and hydrochloric acid, the iron will replace the hydrogen. In *double decompositions* two compounds react to form two new compounds. Thus, silver nitrate and sodium chloride react, and the result is silver chloride and sodium nitrate. In such and similar reactions new chemical substances arise

which possess relative stability; and all these processes are characterized by a great difference in properties, by definite proportions of substances, and by a change in energy content.

THE TABLE OF ELEMENTS

Each element is distinguished from every other by definite physical and chemical properties, such as specific gravity, melting point, boiling point, ductility, malleability, compressibility, hardness, coefficient of expansion, refractive index, density, heat of combustion, heat of formation, conductivity of electricity and heat, combining weight, etc. Some elements are rare, others appear in great quantities; some are dense, others are diffuse; some are found under ordinary conditions in a free state, some always in compounds, some both free and in compounds; some appear under ordinary conditions as solids, some as liquids, some as gases; some are metals, others are nonmetals; some are active, others inert; some are normally radioactive, but most are not.

The elements are arranged in a progressive series called the *Table of Elements*. The position or place in the series determines the element's atomic number. (See Periodic Table) The place of all elements in the table depends, generally speaking, on their *atomic weight*. By an *atom* chemists and physicists understand the smallest particle of an element into which the element can be divided chemically while still remaining a portion of this particular element. It is the smallest particle of an element which can

exist for itself or combine with other similar particles to form a molecule. A *molecule* is the smallest portion of a compound or, if an element can exist in the free state, of an element. Since a compound is composed of at least two elements, no molecule of a compound can consist of less than two elemental atoms; if the compounds are more complex in their chemical composition, their molecules must be proportionately more complex. By *atomic weight* scientists mean the *relative weight* of an element compared with that of oxygen taken as a standard.

TABLE OF ELEMENTS AND THEIR ISOTOPES														
Note: The numbers under the heading 'Isotopes' represent the number of isotopes of this element so far discovered; each number stands for the atomic weight of such an isotope. These isotopes which constitute 70 or more per cent of the total quantity of the isotopes of any element are printed in italics. (S) signifies that an element is 'simple' or pure, with no isotopes discovered. Blank spaces indicate lack of knowledge or the inability to investigate this particular element.														
At. No.	Element	Symbol	Atomic Weight	Isotopes	At. No.	Element	Symbol	Atomic Weight	Isotopes	At. No.	Element	Symbol	Atomic Weight	Isotopes

Table of Elements

ISOTOPES

Frederick Soddy pointed out that the element lead appeared with different atomic weights, the lead derived from thorium having a weight different from that derived from uranium, although both forms of lead possessed the same chemical properties. This might explain the fractions involved in the numbers of so many atomic weights, because the samples, of which the weights were taken, would be mixtures of elements of both weights. If a greater abundance of one kind were present in the mixture, the resulting atomic weight would not be expressed by a whole number, but by a number with a fraction, because it would be an average. Soddy called such elements *isotopes* (Gr., *ἴσος* equal, *τόπος*, place); they occupy the same position in the table of elements, because they are identical in chemical behavior, though they differ in their respective weights.

The problem was attacked systematically by Sir J. J. Thomson with his 'parabola' method of analysis and by *F. W. Aston* by his 'mass-spectrograph' method. The results of these and similar investigations proved conclusively that many elements are isotopic. Thus a very small amount of hydrogen has an atomic weight of 2 instead of 1, and this accounts for the existence of 'heavy water,' although it is really a case of 'heavy hydrogen' rather than of 'heavy water.' This isotopic form of hydrogen is also called 'deuterium,' with atomic weight 2. Tin which is given in the table of elements as having an atomic weight of 118.70, has eleven isotopes, beginning with 112 and ending with 124. Mercury (at. wt. 200.61) consists of nine isotopes, and lead of eight. Even oxygen, whose atomic weight is standard, is

not a simple or pure element, but appears in three isotopes, namely 16, 17, 18. At least 20 of the elements are considered to be 'simple,' i.e., not isotopic; their weights, for all practical purposes, are expressed in whole numbers.²

A glance at the list of isotopes (see Table), reveals the interesting fact that, with a few exceptions, there is a practically *uninterrupted progression* in atomic weights from 1 (hydrogen) to 238 (uranium). The examination of the isotopic condition of elements is far from complete, and more extensive investigations will no doubt succeed in filling some of the intervening gaps. The significant point should be noted that isotopes of adjacent elements *frequently overlap in their respective weights*. Up to chlorine (at. no. 17, at. wt. 35.457) the weights are in clear progression, without overlapping. But from chlorine on, the weights of the isotopic elements overlap in most cases, reaching back over the atomic weight of the preceding element and forward over the weight of the one following.

Another peculiarity in connection with isotopes is the variation in the *percentage of abundance* for the isotopes of the same element. For example, 99.81 per cent of oxygen has a weight of 16, while only 0.03 per cent has a weight of 17 and 0.16 per cent weight of 18. In the case of hydrogen the proportion is 99.9 with an atomic weight of 1, and 0.003 with an atomic weight of 2. Magnesium appears with isotopes of atomic weights 24, 25, and 26; the percentage of abundance for these isotopes, in the order mentioned, is 77.4, 11.5, and 11.1. Chlorine has isotopes of atomic weight 35 and 37; the percentage for these is 76 and 24. The

standard atomic weight of magnesium is 24.32, and of chlorine 34.457 the large fractions of these two elements is thus explained by the difference in the percentage of abundance of their isotopes. A similar condition prevails among all isotopic elements.

Perhaps even more remarkable than the overlapping of the atomic weights of isotopes is the *inverted order* of a few elements in the table. Argon (at. wt. 39.944) is placed before potassium (at. wt. 39.10); cobalt (at. wt. 58.94) before nickel (at. wt. 58.69); tellurium (at. wt. 127.61) before iodine (at. wt. 126.93); and thorium (at. wt. 232.12) before protoactinium (at. wt. 231). If the progression in atomic weights is the reason for the order of the elements in the table, this procedure is most irregular. Formerly, the atomic weights were looked upon as the main feature of the elements, and the elements received their place in the table accordingly. Now, however, the atomic weights of the elements are considered to be of secondary Importance in distinguishing one element from another. The elements, as elements, are chiefly distinguishable through their chemical and physical behavior and properties. These factors determine their succession in the table. This will be understood more clearly from a study of the Periodic Law.

THE PERIODIC LAW

The 'whole number' rule, as it exists in atomic weights, shows that there is a definite relationship among the elements. When we turn our attention toward a comparison of the elements from the standpoint of their chemical and

physical behavior and properties, we discover a relationship which is far more intricate and profound. Consult the *Periodic Table*. This chart or plan of the elements owes its origin to the genius of D. Mendeléeff, who published his observations and theories in 1869—1871. Though his plan has been modified in certain important details, the plan as such has survived the test of the years and is universally accepted. As the elements are arranged according to their advancing atomic weights, there is at intervals a regular recurrence of elements possessing similar properties, so that such similarities occur in cycles or periods. This periodic recurrence of similar elements is styled the *Periodic Law of Elements*. Mendeléeff arranged the elements into 'series' and 'groups' which show at a glance to which class a particular element belongs. His arrangement left many gaps between the elements as then known, and he predicted the existence of a number of elements to fill these gaps, together with the chemical properties which he claimed they must possess; subsequent discoveries verified his predictions.

The periodic table is divided into groups (families) and series (periods), In the table the 'groups' run vertically, and the 'series' horizontally. A *group*, or *family*, is a class of chemically similar elements. A *series*, or *period*, is a sequence of elements which begin with a group and advance according to their increasing atomic number, until an element is reached which is similar to that of the group from which the sequence started, thus completing the cycle or period.

At the time when Mendeléeff announced the periodic law, he based his table on the principle that the *properties* of elements are *periodic functions of their atomic weights*. Hereby he stated that, if elements are arranged according to their increasing weights, elements with similar properties would recur periodically. This is not true, because, as we have seen, the isotopic weights of different elements overlap, although their properties remain the same. Furthermore, the ‘group’ relationship of argon and potassium, cobalt and nickel, tellurium and iodine, thorium and protoactinium, would of necessity be reversed, placing each in a wrong group, thereby overthrowing the very periodicity which Mendeléeff sought to establish with this principle. The properties of the elements cannot, therefore, be functions of their atomic weights. *Moseley*, 1912—1914, established a new periodic law on the principle that the properties of elements are *periodic functions of their atomic number*. Moseley’s principle corrects the irregularities inherent in Mendeléeff’s system and shows that the atomic number, and not the atomic weight, is the decisive factor in distinguishing and arranging the elements. Modern periodic tables are therefore built up on Moseley’s new periodic law of atomic numbers.

According to this method of arrangement there are nine groups or families; and there are seven series or periods of unequal length. The various series contain the following elements:

Series ———Number of Elements

1.2

2.	8
3.	8
4.	18
5.	18
6.	32
7.	6

Confining ourselves to the first six series, the sequence of places is 2-8-8-18-18-32. The periodicity of the elements is plainly demonstrated here, because these numbers are $2 \times 1^2 = 2$, $2 \times 2^2 = 8$, $2 \times 3^2 = 18$, and $2 \times 4^2 = 32$. The periodic table is thus seen to follow a definite plan.

That this arrangement is not arbitrary, becomes evident from a closer scrutiny of the groups and series.

THE PERIODIC GROUPS

In the periodic table the 'groups' or 'families' are vertical rows of elements possessing similar physical and chemical properties. In comparing the groups among themselves, it is best, for the present, to omit Group O and Group VIII and restrict ourselves to the groups from I to VII. Similarly, it is advisable to leave hydrogen aside for the moment. The reasons for this procedure will become apparent later.

Group I consists of lithium (Li), sodium (Na), potassium (K), rubidium (Rb), and caesium (Cs), and their properties are highly similar. Group VII consists of fluorine (F), chlorine (Cl), bromine (Br), and iodine (I), and here we also discover a very close resemblance in their properties. Group I contains the alkali metals which form basic

compounds, while Group VII contains the halogens which form acidic compounds. These two groups, therefore, represent the two great classes of elements, the metals and the nonmetal; the bases and the acids. As we go forward from Group I toward the middle of the group, Groups II and III become less metallic and less basic in character; and as we go backward from Group VII toward the middle of the group, Groups VI and V become less nonmetallic and less acidic in character. The middle members of the groups, therefore, show the features of both basic (metallic) and acidic elements. Arsenic, tin, and aluminum, for example, form both acid and basic compounds. The sequence of the groups passes, therefore, through gradual stages from the metallic to the acidic elements.

THE PERIODIC TABLE

The Periodic Table

Another feature of the various groups, when compared with one another, is their difference in *electric character*. Beginning with Group I, the first groups are *electric-positive* i.e., in an electrolytic solution these substances travel to the negative pole or cathode. The latter groups are electronegative; they seek the positive pole or anode in electrolysis. In other words, the basic groups of elements, situated toward the left-hand side of the periodic table, give up positive ions (cations) in an electrolytic solution, while the acidic groups, toward the right-hand side, give up negative ions (anions).

Since the *physical properties* flow naturally from the chemical, a periodic recurrence of physical properties among the members of the various groups is also found to exist. Such properties are: density, atomic volume, vibration frequency, malleability, conductivity of heat and electricity, etc.

While the periodicity of the elements is unquestionably well established, this recurrence of similar elements is not a mechanical repetition. Some groups possess greater resemblance in their members than others. The members of a group correspond to the characteristics of the group only in a general way; in some instances the resemblance is rather slight. The resemblance decreases as the length of the series increases and as the elements become more complex. As we pass down the list of the groups vertically, all groups manifest a decided tendency to become more basic (metallic) and less acidic. This is noticeable, for example, with regard to selenium and tellurium in Group VI, and even more so with regard to tantalum and proto-

actinium. Furthermore, the last members of each group in the final series, so far as their representatives are known, are radioactive; radioactivity is a property which is absent in the other elements. In general, however, though there are some irregularities and dissimilarities among the members of the various groups, the law of periodicity holds true.

The *Zero elements*, those of *Group 0*, namely helium, neon, argon, krypton, xenon, and radon, occupy an odd position in the periodic table. They were not discovered until a comparatively recent date. They are rare gases, chemically inert, with no tendency to combine with other elements, and electro-neutral. At first it was considered difficult to find a place for them in the periodic table, because they were so different from the other elements. They fit admirably, however, into the general scheme and were designated the 'Zero elements,' Group 0. There is still considerable divergence of opinion as to whether this group should be placed at the beginning or at the end of the other groups, but that is of minor importance. All agree that the Zero elements belong in a position between the halogens and the alkali metals, between Group VII (VIII) and Group I. They form the natural dividing line between one series and the next, and they thus become the logical point of reference for the elements preceding and following them. These gases bear strong resemblances to each other and form a very striking group.

Group VIII consists of three triads of elements. The members of each triad are closely related and form a distinct group among themselves. Their position as a group

in the periodic table will be explained in the discussion of the various 'series.'

It is because of 'group resemblance' that the four pairs of elements occupy *inverted positions* in the periodic table, so that the heavier element precedes the lighter. Judged according to their atomic weights, argon should follow potassium. Argon, however, is an inert gas which resembles neon in all respects; potassium is a very active, electropositive metal, which plainly belongs to the same group as lithium and sodium. The same consideration applies to nickel and cobalt, iodine and tellurium, protoactinium and thorium; their properties demand that they be placed in these respective groups in the table. Chemical properties, rather than atomic weights, are the distinguishing features of the elements.

THE PERIODIC SERIES

A periodic *series* is a sequence of elements arranged horizontally in the periodic table, in such a manner that these elements increase one by one in their atomic number; each series begins with a member of Group I and continues progressively until the sequence reaches the next inert gas in Group 0. After this cycle or series is finished, the next series begins. The *Zero elements* (Group 0) form a natural limit for each series. They are followed immediately by the basic or metallic elements of Group I, which in turn gradually give way to the acidic elements. These latter are followed by another element of Group 0.

The series are of unequal length. The *first series* contains but two elements, hydrogen (H, at. no. 1) and helium (He, at. no. 2). Hydrogen is the fundamental element, very active, and possesses characteristics of both the basic and acidic elements. Its position among the elements is unique, and it has therefore a place more or less for itself in the periodic table; strictly speaking, it does not belong to any particular group. Helium is an inert gas, the first of Group 0, with an atomic weight four times that of hydrogen (at. wt. 4.0022). The *second series* is a 'short' series of *eight* elements, lithium (Li), beryllium (Be), boron (B), carbon (C), nitrogen (N), oxygen (O), fluorine (F), leading to the next member of Group 0, neon (Ne, at. no. 10). The third series is also a 'short' series of eight elements, sodium (Na), magnesium (Mg), aluminum (Al), silicon (Si), phosphorus (P), sulphur (S), chlorine (Cl), ending with argon (A, at no. 18) the third member of Group 0. There is nothing complicated about these short series; they contain typical elements of the basic and acidic groups in their proper order. The following series present difficulties.

The *fourth series* is a 'long' series, and it contains eighteen elements, from potassium (K, at. no. 19) to krypton (Kr, at. no. 36). This series has a triad of elements, iron (Fe), cobalt (Co.), and nickel (Ni), in Group VIII; they are the first of the three triads which appear in this group, and they bear a close resemblance to each other. This is not the only irregularity of this series. Potassium (K) resembles sodium and lithium in Group I, as is to be expected; and calcium (Ca) resembles magnesium and beryllium in Group II. But

here the resemblance ends. Scandium (Sc), titanium (Ti), vanadium (V), chromium (Cr), and manganese (Mn), should belong to the acidic groups; they are, however, distinctly metallic in character. These elements, together with iron (Fe), cobalt (Co), nickel (Ni), copper (Cu), and zinc (Zn), are metallic elements. It is only when we reach gallium (Ga), germanium (Ge), arsenic (As), selenium (Se), and bromine (Br), that the elements correspond again to Groups III, IV, V, VI, and VII of the typical eight-element series and become acidic. If the ten elements, scandium to zinc (at. no. 21—30), were omitted, this series would be in perfect agreement with the two preceding short series. As it is, the sequence is interrupted with calcium, and ten new elements are interpolated, before the regular sequence is resumed with gallium (at. no. 31). These interpolated elements are now considered to be *transitional elements*. It is only as a matter of convenience that they are placed in the periodic table as if they were members of the other regular groups; they should have a place of their own between Group II and Group III. The lithium and sodium series are standard and typical, and so this long series, with its interpolated and transitional group of ten elements, is made to conform to their general scheme of arrangement.

The *fifth series* is also a 'long' series of eighteen elements, from rubidium (Rb, at. no. 37) to the inactive gas xenon (X, at. no. 54). The sequence is the same as in the foregoing long series. The first two elements, rubidium and strontium (Sr, at. no. 38) are in agreement with the first two groups of the lithium, sodium, and potassium series. Then follow ten *transitional* elements, yttrium (Y), zirconium (Zr),

niobium (Nb), molybdenum (Mo), masurium (as yet not entirely certain), ruthenium (Ru), rhodium (Rh), palladium (Pd), silver (Ag), and cadmium (Cd). These occupy the same positions as the ten transitional elements in the long potassium series. From this point on the elements become more acidic, namely indium (In), tin (Sn), antimony (Sb), tellurium (Te), and iodine (I), although indium and tin are metals and antimony has metallic and nonmetallic properties. Xenon ends the series. In this series we again observe a triad in Group VIII, considered as a unit, ruthenium, rhodium, and palladium. This entire series is analogous to the potassium series, and also, if we omit the ten transitional elements, analogous to the standard, typical lithium and sodium series.

The *sixth series*, from caesium (Cs, at. no. 55) to radon (Rn, at. no. 86, or, as it is also called, emanation, Em), is the 'longest' series and contains *thirty-two* members. Here again, the first two elements, caesium and barium (Ba) coincide with the metallic elements of Groups I and II of all the preceding series. These are followed by lanthanum (La) and fourteen other rare earth elements, a new group of transitional elements characteristic of this series. These rare earths have such a close resemblance, that it has proved an extremely difficult chemical task to isolate them from each other and establish their separate identity. We then have hafnium (Hf), tantalum (Ta), tungsten (W), rhenium (Re), osmium (Os), iridium (Ir), platinum (Pt), gold (Au), and mercury (Hg); these, together with lanthanum, are a sequence of elements which correspond to the ten transitional elements found in the two preceding 'long'

series. This caesium series also has a triad in Group VIII, namely osmium, iridium, and platinum, closely related as to properties, similar to the triads of the potassium and rubidium series. After these interpolated elements we have thallium (Tl), lead (Pb), bismuth (Bi), polonium (Po), and an undiscovered element of atomic number 85. Of these, thallium, lead, and bismuth are metallic; polonium is again acidic, and so, in all probability, is the undiscovered element. As will be noticed, the entire series is practically a basic, metallic series; it shows definitely that, as the elements become heavier and more complex in structure, they become less and less acidic. The class of rare earths are usually given a single place in the periodic table. This is permissible, because they are so closely related. In general, however, violence is done thereby to the arrangement of the periodic table. The acidic groups, so clear and marked in the 'short' lithium and sodium series, lose many of their characteristic features in the members of the 'long' potassium and rubidium series, and still more in this 'longest' caesium series; few elements of the higher atomic numbers are acidic.

The *seventh series* contains only six elements, an undiscovered element of atomic number 87 (ekacaesium), radium (Ra), actinium (Ac), thorium (Th), protoactinium (Pa), and uranium (U). Radium resembles barium, strontium, and calcium. Actinium is an analogue of lanthanum. Thorium, protoactinium, and uranium correspond to zirconium, niobium, and molybdenum. Uranium (at. no. 92, at. wt. 238) is, as far as is known, the last of the stable elements. All are *radioactive metals* and in

a Continuous process of disintegration. This may be an indication that this series originally contained a much larger number of elements, of which most have been lost in the course of the ages through conversion into lighter elements. Some scientists are of the opinion that this series was composed of 32 elements, corresponding in number to the caesium series. Others consider this improbable, because the series, so far as its present members are concerned, is more in accord with the rubidium than with the caesium series. At any rate, the last series is considered to be an incomplete series of disintegrated and disintegrating elements.

THE PROBLEM OF PERIODICITY

As we study the periodic table, we cannot deny the fact that periodicity, or a recurrence of elements with similar properties, actually occurs. The inert gases of Group 0 are the *key-elements* which occupy the positions of importance in the whole table; they are stable, electroneutral, inactive, manifesting no affinity for other elements, and have no tendency to combine with others to form compounds. All others are electropositive or electronegative, basic or acidic, metallic or nonmetallic, and combine with others to form compounds. A definite number of series or periods is thus found to exist, starting from an inert gas and ending with the next inert gas.

As early as 1914 *Rydberg* called attention to the fact that the atomic numbers of these Group 0 gases can be

calculated from a series of numbers now called the *Rydberg Series*, expressed in the simple formula:

$$2(1^2 + 2^2 + 2^2 + 3^2 + 3^2 + 4^2 \dots)$$

According to this formula we obtain the following results:

- Element At. No. Rydberg Series
- Helium.....2..... $2(1^2) = 2$
- Neon.....10..... $2(1^2 + 2^2) = 10$
- Argon.....18..... $2(1^2 + 2^2 + 2^2) = 18$
- Krypton.....36..... $2(1^2 + 2^2 + 2^2 + 3^2) = 36$
- Xenon.....54..... $2(1^2 + 2^2 + 2^2 + 3^2 + 3^2) = 54$
- Radon.....86..... $2(1^2 + 2^2 + 2^2 + 3^2 + 3^2 + 4^2) = 86$

This striking fact cannot be accounted for by mere chance; the product of the calculation is too perfect for that. It is plainly a case of periodicity.

We must come to the same conclusion when we compare the series with each other. We discover a remarkable *parallelism*. The first series, that of hydrogen and helium, is unique. One element is active, and the other inert. This small series of two epitomizes within itself all the subsequent series of the periodic table. The lithium and sodium 'short' series are parallel in nearly all respects, each containing 8 elements. The potassium and rubidium 'long' series are also parallel to each other, each consisting of 18

members, of which 10 are transitional. The caesium 'longest' series is composed of 32 elements. If the last, radioactive series, as some scientists believe, also had originally 32 elements, the parallelism would be complete; but this is only a conjecture. There can be no question, however, about the periodicity involved in the parallelism manifested in the two 'short' and in the two 'long' series.

How can this *periodicity be explained*? Such regularity of recurrence must be based upon some fundamental *similarity of atomic structure* within the elements themselves. This follows logically from the entire arrangement of *groups* and *series* and from the steady progression of *atomic weights*. There must exist a profound relationship between the advancing increase in atomic weight, the atomic structure, and the periodic recurrence of similarity in the elements and their properties. At the same time, something must be found in the atomic structure of the elements which is able to account for the isotopes and the irregularities found to exist between certain atomic numbers and atomic weights, since these irregularities apparently disturb the proper sequence of the table.

Scientists are convinced that they have found the answer to these questions in the internal structure of the atom itself. Instead of 92 ultimate material constituents of the universe, scientists have discovered that all elements consist alike of certain fundamental particles of matter. Even the atom is not a simple material substance, but a complex structure. We must now investigate the elemental

atom and see whether we can there discover any clues to the ultimate constitution of physical bodies.

SUMMARY OF CHAPTER II

1. *Matter and Energy.* Matter is anything that occupies space. Energy is the capacity for performing work; it is either potential or kinetic.

2. *Elements and Chemical Compounds.* An element is any material substance which cannot be resolved by ordinary chemical means into two or more similar substances different in nature from itself. A chemical compound is a substance composed of two or more elements chemically combined in definite proportions by weight.

3. *The Table of Elements.* Elements are distinguishable by definite physical and chemical properties. The atomic number represents the Position of each element in the Table of Elements. This position is determined, generally speaking, by the atomic weight of the element, i.e., the relative weight of an element compared with that of another element taken as a standard. The standard is oxygen, with an atomic weight of 16

4. *Isotopes.* Not all elements are pure; they have different weights, though their properties are identical, and these are called isotopes. Isotopes show that the atomic weights of the elements progress in 'whole numbers.'

5. *The Periodic Law.* It is the periodic recurrence of similar elements in the table of elements. The periodic table is arranged according to *groups* and *series*. There are nine groups and seven series. A 'group' is a class of chemically similar elements. A 'series' is a sequence of elements which begin with a group and advance according to their

increasing atomic number, until an element is reached which is similar to that of the group from which the sequence started. The 'periodic law' states that the properties of elements are the periodic functions of their *atomic number*, not of their atomic weight.

6. *The Periodic Groups.* The periodic groups from I to VII represent the two great classes of elements, *metals* and *nonmetals*, bases and acids. As the groups proceed forward from Group I, they become less basic; as they go backward from Group VII, they become less acidic. The middle groups show basic and acidic features. The groups toward the metallic side of the table are *electropositive*; those toward the acidic side are electronegative. Group 0 contains the *inert gases*, while Group VIII contains three triads of metallic elements.

7. *The Periodic Series.* The periodic series contain elements in sequence between one Zero element and the next Zero element. The number of elements in the succeeding series is as follows: 2, 8, 8, 18, 18, 32, 6. The 18, 18, and 32 series contain respectively 10, 10, and 24 transitional elements. The final series is an incomplete, radioactive series.

8. *The Problem of Periodicity.* The periodicity of the elements is an unquestionable fact. Since the reason for the periodic recurrence of similar elements does not lie in their weights, it must be due to the similarity of *atomic structure*.

Chapter 3

ATOMS AND SUBATOMIC PARTICLES

THE MIND OF MAN HAS ALWAYS SOUGHT TO REDUCE THE multiplicity of things to simpler units. The enormous multitude of living and nonliving bodies did not escape this unifying and simplifying tendency of the mind. *Thales* conceived the idea that all bodies are but modifications of one fundamental element, water. His idea, however, seemed to carry the principle of reduction too far. *Aristotle* advocated five ultimate elements, and his views dominated the minds of medieval thinkers. Modern chemistry endeavored to solve the problem by means of a strictly scientific, experimental analysis of chemical compounds. The result was amazing. Instead of being able to resolve all types of bodies into a few elements, chemists were forced to admit the existence of about 92 irreducible elements as the ultimate constituents of nature. However, the periodic recurrence of definite groups of elements pointed to some underlying principle of unity among them. Just what this principle might be, no one for a time seemed able to conjecture.

It was reserved to the scientists of our own generation, through a deeper knowledge of *electricity*, to effect a

reduction of the 92 elements to a few fundamentally distinct types of matter as their common components.

ELECTRICITY

To the genius of *Faraday* goes the credit of having first uncovered experimental evidence which showed that electricity must be essentially atomic. In his experiments with chemical electrolytes, he found, in 1833 and after, that a solution containing, for example, a hydrogen compound reacted to a definite amount of electric current in such a way that under all conditions the same amount of hydrogen made its appearance at the negative electrode.

To illustrate. In order to release 1.0078 grams of hydrogen out of a solution by depositing it at the electrode, a quantity of electricity amounting to a faraday, or 96,494 coulombs,¹ will be required. But this same quantity will also deposit 107.88 grams of silver out of a silver nitrate solution. Hydrogen and silver are univalent elements. Now, the atomic weight of hydrogen is 1 and the atomic weight of silver is 107.88. Consequently 1.0078 grams of hydrogen and 107.88 grams of silver contain an equal number of atoms, and each atom of both elements must carry an equal charge or quantity of electricity in the solution. It has been estimated that the number of atoms of hydrogen in 1.0078 grams is 6.064×10^{23} (606,400,000,000,000,000,000,000); there are, of course, the same number of silver atoms in 107.88 grams of silver. If we now divide the 96,494 coulombs by this number, we obtain the charge on a single atom: this charge is 15.9×10^{-20} coulombs

(0.000,000,000,000,000,000,159). This is equivalent to 4.77×10^{-10} electrostatic units. Copper being a bivalent element with an atomic weight of 63.57, it requires two faradays ($2 \times 96,494$ coulombs) to deposit 63.57 grams out of a solution; 1 faraday will deposit half this amount, namely 31.8 grams. Since iron in a ferric solution is trivalent, it requires three faradays to deposit an amount in grams equal to the number of its atomic weight, 55.84; one faraday would deposit one third of this, and two faradays two thirds.

These processes are invariable, and the unit charge is constant. Fractions never occur; the charges are found only in unit charges or in exact multiples of it. The conclusion to be drawn from these facts seemed obviously to be that electricity exists in unitary quantities and must therefore be atomic in its constitution.

Faraday, however, did not draw this conclusion. On the contrary, he favored and defended the theory that electricity consists in *stresses and strains* in the medium surrounding the electrified bodies; the carrier of electricity was the *aether*. To a very great extent this theory was based on the presence of electric fields in cases of electrification. The 'aether-stress theory received strong support from the discovery in 1887 by Hertz that electricity does not require metal conductors but could travel with the speed of light in the form of electric waves. This phenomena seemed inconsistent with the idea of electricity as atomic in character. The 'aether-stress' theory prevailed until the turn of the century, mainly through the efforts of *Clerk-Maxwell and Sir Oliver Lodge*.

In 1895 *Röntgen* discovered *X rays*, and with them he furnished scientists with an instrument of research which revolutionized physics and unraveled many of the mysteries of electricity and of the constitution of the elements. X rays remain unaffected by electric and magnetic fields and are of the nature of light, not of electricity. They are produced in a vacuum tube, when some dense metal, such as tungsten or platinum, is exposed to a stream of rays which emanate from the cathode, or negative electrode, of the tube. These so-called *cathode rays* possess the characteristics, not of waves, but of electric particles. They are deviated from a straight course by a magnetic or electric field, being repelled by a negative field and attracted by a positive field; they have, therefore, negative charges. When directed onto a conductor leading to an electrometer, the conductor shows a negative charge. If these cathode rays fall upon the glass wall of the tube as a target, the glass becomes fluorescent; and if a strong stream impinges for some time upon the target, the target becomes pitted and even incandescent. To produce such effects, the cathode rays must consist of *material particles*, with a negative charge, possessing considerable force of impact. Flowing in the Opposite direction and emanating from the anode, or positive pole, is a stream of particles which have a positive charge; they are called *canal rays* and are the counterpart of the cathode rays. Both types of rays are unidirectional, i.e., they travel in one direction only: the cathode rays travel away from the cathode, and the canal rays travel away from the anode, but never in the reverse direction.

THE ELECTRON AND PROTON

What is the *origin* of the cathode and canal rays? Of what *kind of matter* do they consist? Have they *mass and velocity*? Extensive experiments have been made, and the answer to these questions has been found.

No matter what kinds of elements or compounds are used as electrodes, and no matter what kinds of gases are used in the vacuum tube, the cathode rays are always produced and they always act in the same manner. Every kind of element or substance yields these negatively charged particles. They now go by the name of *electrons*.

When hydrogen gas is used in a tube under low pressure and a current of sufficient strength passes through the gas, a stream of electrons (cathode rays) is generated, traveling in the direction away from the cathode. The canal rays are then observed to consist of hydrogen ions with a positive charge. Since the hydrogen atoms are normally neutral, so far as their electric charge is concerned, it is obvious that the hydrogen atom must consist of two types of matter, one carrying a positive charge (the positive ion) and the other a negative charge (the electron). Since hydrogen is the simplest and lightest of all elements, and since its atom never loses more than a single negative charge (an electron), it must be assumed that the positive hydrogen ion also consists of a single portion of matter carrying a unit charge of positive electricity. This positive hydrogen ion, therefore, is the exact counterpart of the negative electron, and is called by a special name, the proton. Consequently, it is assumed on very strong evidence that the hydrogen atom

consists of two distinct particles of matter of equal, but opposite, electrical charges, a *proton and an electron*; together they form the electrically neutral hydrogen atom.

The proton and the electron represent the minimal, elementary unit charge of electricity. They differ, however, greatly in *mass*. It is impossible to describe here the ingenious methods which scientists have devised for the measurement of the mass of the various atoms. Suffice it to say that the methods are based on the deflection of particles in an electric and magnetic field. The hydrogen atom has a mass of 1.6617×10^{-24} grams; of this total mass 1.6608×10^{-24} grams goes to the proton, and $0.0008994 \times 10^{-24}$ grams to the electron. The mass of the electron is about 1/1845 of the mass of the hydrogen atom; in other words, the proton, or particle with positive charge, contains practically all the mass or weight which is found in the hydrogen atom, while the mass or weight of the electron in the hydrogen atom is practically negligible. The same applies, of course, to the atoms of the other elements. From this it follows that the atomic weights of the elements are determined, not by the electrons, but by that portion of the elements which possesses the positive charge. Notwithstanding the difference in mass between the proton and the electron, their electric charge is *equal in value and quantity*; otherwise the normal hydrogen atom would not be electrically neutral. Furthermore, no matter from whatever substance and from whatever source we obtain these electrons, *the mass and charge of the electron* is always the same. This charge, determined by many thousands of experiments and by diverse methods, is

calculated to be 4.77×10^{-10} electrostatic units.² Science designates this charge by the letter e .

As for the size of the electron, its radius is estimated to be approximately 1.9×10^{-13} centimeters, while that of an atom is about 10^{-8} centimeters. Electrons travel at varying velocities, from about one thirtieth to one third the speed of light, or 109 to 1010 centimeters per second, depending upon the voltages across the electrodes of the X-ray tube.

Various experiments and the calculations based on them bring out the important fact that the charge carried by *gaseous ions* is identical with the charge carried by *ions in liquid electrolytes*, namely a unit charge of 4.77×10^{-10} electrostatic units. And this unit charge varies in exact multiples of the unit charge, 2, 3, 4, 5, and so on. A positive ion is thus nothing but an atom from which one or more electrons have been separated, leaving a net positive charge on the residue; and a negative ion is an atom which has taken on one or more electrons, giving it a net negative charge. The ionization of gases and liquid solutions now receives an adequate explanation, and both processes confirm the view that atoms are not simple entities but *complex structures consisting of positively and negatively charged particles of matter*, and that electricity is *discrete and atomic* in character.

ALPHA, BETA, AND GAMMA RAYS

In 1896 *Becquerel* made the discovery that certain compounds of uranium were radioactive, emitting rays which resembled X rays. Soon after, in 1898, *Marya*

Skłodowska Curie and her husband Pierre discovered radium and other substances more radioactive than uranium. The study of their radiations by numerous scientists, especially by *E. Rutherford* and *Sir Joseph Thomson*, disclosed the fact that these radiations were qualitatively very diverse. They are of three types, and are called alpha (α), beta (β), and gamma (γ) rays, the names being taken from the first three letters of the Greek alphabet. When exposed to a magnetic field, the rays behave in a manner indicated by the diagram:

The *alpha* rays are seen to be deflected to a slight degree and to end abruptly at a certain distance from the source. They are positively charged and possess all the characteristics of material particles. With respect to mass they possess a mass equal to that of a helium atom or four protons, and a charge which is twice that of an electron, namely 9.54×10^{-10} e.s.u.; later we will see that they really are helium atoms shorn of two electrons, leaving a net positive charge of $+2e$. Of the three types of rays they have the least effect upon a photographic plate. A few centimeters of air at standard pressure or one tenth of a millimeter of aluminum absorb them completely. On the other hand, they have an intense power of ionization in gases. Due to their mass and great kinetic energy, they deviate but slightly in a magnetic field. Their velocity is anywhere from 9-14,000 miles per second, i.e., from one thirteenth to one twentieth of the speed of light, depending upon the energy of the

radioactive substance from which they emanate. Alpha particles play a prominent part in radioactivity and in the interpretation of atomic structure.

Beta rays are identical, except for greater velocity, with the cathode rays generated in the vacuum tube; that is to say, they are electrons, having the same negative charge and the same mass. The electrons of the cathode rays seldom attain a velocity greater than one third to one half that of light, while the beta particles (electrons) of radium reach the tremendous velocity of 98 per cent of light. Compared to the alpha particles, their ionizing power is small, while their penetrating power is greater; they can pierce a plate of aluminum which is one centimeter thick. In a magnetic field beta rays can be bent into circles, the swifter rays having the larger diameter.

The *gamma rays*, since they pursue their course without being affected by a magnetic or electric field, are not particles; they are rays similar in nature to X rays, but of shorter wave length. Gamma rays have a wave length of less than 10^{-9} centimeters, while X rays usually range between 10^{-9} and 10^{-8} centimeters; it is possible, however, to generate very 'hard' X rays with a shorter wave length than that of some gamma rays. Both the gamma rays and the X rays are of considerably shorter wave length than the common ultraviolet rays, the latter usually having a wave length of about 10^{-5} centimeters; all three types are electromagnetic in character. Gamma rays possess slight powers of ionization. They are, however, very penetrating; some of the more powerful can pierce 20 to 30 centimeters of iron or 8 to 10 in. of mercury or lead.

The alpha, beta, and gamma rays are active chemically and produce marked effects on many substances in their immediate vicinity. Their effect on the photographic plate and their decomposition of many compounds prove this conclusively; water, for example, is resolved into hydrogen and oxygen, air is formed into ozone and various oxides of nitrogen, and carbon compounds are changed into carbon dioxide and monoxide. The medicinal qualities of radium and other radioactive substances are entirely due to these rays.

COSMIC RAYS

In 1910 *Gockel* noted that an electroscope, when taken in a balloon to 4500 meters, had a rate of discharge which was higher than on the earth. This seemed to indicate the presence of rays which reached the earth from interstellar space; and since this discharge was apparently the same during the night as during the day, it could not be due to the radiation of the sun. Between the years 1922 and 1925, *Millikan*, *Otis*, and *Cameron* made some crucial experiments which seem to prove conclusively that there are rays which come from the outer space of the cosmos, pierce the entire atmosphere, penetrate water down to a depth of fifteen and more meters, and discharge an electroscope. These are the so-called *cosmic rays*. They have a penetrating power which is eighteen times more than that of the most penetrating gamma rays. It is estimated that nearly one half of the energy which strikes the earth in the form of light and heat from the stars is due

to cosmic rays. That this energy does not come from the Milky Way, was shown in localities where the Milky Way is not visible, the amount of cosmic rays being just as great under both conditions; the rays are, to all appearance, distributed uniformly and equally throughout space, because they come in from all directions. The source of these rays, therefore, so far as our present knowledge goes, lies in interstellar space, and not in the sun, stars, or nebulae.

The intensity and penetrating power of cosmic rays vary considerably, showing that they are not all alike. Experiments made in Gem Lake, California, revealed the presence of cosmic rays at a depth of 235 ft., a capacity of penetration equivalent to penetrating more than 20 ft. of lead; *Regener* recorded them at a depth of about 700 ft. of water. The most penetrating of the gamma waves are absorbed at a depth of about 6 ft. of water. Since the energy required to give such penetration to a gamma ray amounts to 2.6 million electron volts,³ the energy evolved to give such enormous penetration power to cosmic rays is proportionately greater and amounts often to tens of millions of electron volts and, in some instances, to hundreds of millions of electron volts. These calculations are based on the curvature tracks of particles made in the Wilson expansion or cloud chamber. The moisture of the chamber does not settle on uncharged, neutral atoms, but on the ions. An electron, proton, alpha or cosmic ray particle, on passing through the chamber, ionizes the gas; moisture particles condense and settle on these ions, and a visible track or trail of the passage of the ionizing particle

remains which can be photographed. The length and curvature of these tracks are an indication of the power of the particles and enables scientists to determine the type and energy of the particles traversing the chamber. This method of research has led to the discovery of a new kind of particle, the so-called 'positron.' All physicists now agree that the positron actually exists.

The *positron* is a particle or corpuscle of matter equal in mass to an electron, but of *positive charge*. Its existence was first discovered by *Carl D. Anderson* and *Robert Millikan* and its nature definitely established in 1932. Photographs of such positrons passing through a six-millimeter lead plate in the cloud chamber have been taken; the curvature before entering and after leaving the lead shows a corresponding loss of energy, the positron entering with an energy of 63 million electron volts and emerging with an energy of 23 million volts. Since that time thousands of photographs taken have proved that among the electronic tracks of particles of over 100 million electron volts fully half are of free positrons. In all these instances negative electrons (or 'negatrons,' as it has been suggested that they now be called) and positrons were found to be 'identical twins,' the same in every regard except as to their opposite charge.

Since 1933 many experiments have been made to obtain positrons from sources other than cosmic rays. Various substances, as beryllium, lead, aluminum, and carbon, were bombarded with alpha and gamma rays, and all yielded positive results. This would seem to indicate that the positrons have their origin in the nucleus of the atoms,

because it is the nucleus which carries the positive charge. Some of these energies are calculated to be about three billion electron volts.

Positrons, it seems, have a short life. After their kinetic energy is spent, they disappear entirely. Scientists, experimenting with positrons, are inclined to believe that they unite with (negative) electrons and vanish by being converted into gamma rays. If this is so, it would mean that matter is converted into radiant energy. What part the positrons play in the formation of atomic structure is very uncertain. In fact, so far as positrons are concerned, science is only at the beginning of its research, and much remains to be done before anything very definite can be said about their nature.

THE NEUTRON

Another new type of subatomic particles has been discovered in recent years. It is the neutron. It had been known for some time that certain elements could be disintegrated by bombarding them with alpha rays. In 1930 *Bothe* and *Becker* noticed that beryllium and other light elements emitted a highly penetrating radiation when bombarded with the alpha rays emanating from polonium, a radioactive element which does not emit any gamma rays. The coefficient of absorption for this radiation was 0.22 per centimeter in lead. The energy required amounted to something like 7×10^6 volts. This meant that the ray in question was more penetrating than the most energetic gamma ray known in connection with radioactive

substances. Bothe and Becker considered these rays to be gamma rays of exceptionally high power. It was also found by *Irene Curie* and her husband *F. Joliot* that, when these alpha particles fell upon paraffin, wax, and other substances containing hydrogen, protons appeared which had received an energy of something like 4 to 5 million electron volts. Since the protons are hydrogen ions and hydrogen is the simplest element, the phenomenon could not be the result of disintegration but of a collision. In that case, however, it seemed impossible that so much energy could be transmitted to the protons, because that would involve a contradiction in the laws of momentum and energy.

Thereupon *Chadwick*, in 1932, after much research and experimentation, proposed the theory that the alpha particles from polonium, used by Bothe, Becker, Curie, and others in bombarding these elements, collided with the nuclei of their atoms and ejected particles which had the general mass of protons but were uncharged. He proposed the name *neutron* for this particle, because, being uncharged, it is electrically neutral. When a charged particle, such as an alpha ray, electron, or proton, passes through a substance, it encounters a great resistance, due to mutual attraction and repulsion, and this absorbs a great deal of its penetrating energy. A neutral, uncharged particle, however, is neither attracted nor repelled while on its course and thus can travel much farther before its energy is spent. Its progress can be stopped, however, by collision with other atoms, and in that case the simple mechanics of colliding bodies comes into play. A neutron

would be non-ionizing, and its passage through the Wilson chamber would leave no fog tracks. After the collision, however, the ejected alpha rays, electrons, and protons would produce ionization and reveal their presence by means of tracks. In the case of beryllium bombarded by alpha rays, the explanation would be that an alpha particle collides with the beryllium atom, is captured, and a neutron ejected from the atom. It is thus assumed that neutrons form a normal portion of the atoms of all elements except hydrogen (the latter having only a single proton as a nucleus). Subsequent investigations proved Chadwick's theory to be correct. Neutrons exist, and they are now used extensively as bombarding agencies in many laboratory experiments.

The exact *nature* of the neutron is still very much in doubt. All agree that the mass of the neutron is of the order of the hydrogen proton. Some scientists incline to the view that the neutron is a proton with an electron so closely attached to it that the two can scarcely be disassociated. If this view is correct, the neutron is a combination of two oppositely charged particles. Other scientists are of the opinion that the neutron is simply an un-electrified portion of matter which becomes a proton through the addition of a positron. Since free positrons actually exist, this latter view seems to have some evidence in its favor. In the former view the neutron is a complex particle, and in the latter view the proton is a complex particle. In any case, there are now known to be *three distinct fundamental entities* entering into the constitution of bodies. Depending upon the nature of the neutron and proton, one must accept either (1)

electrons, positrons, and neutrons; or (2) electrons, positrons, and protons.

SOME OTHER PARTICLES

In the last few years, scientists speak with considerable conviction about the existence of a number of other subatomic particles. There is the *mesotron*. Some physicists call it the '*barytron*' or the '*yukon*.' The discoverers, C. D. Anderson and S. H. Neddermeyer, gave it the name 'mesotron,' and this name is now generally accepted. Its mass is intermediate between that of the proton and electron, and so the name mesotron' is appropriate. The mesotron is something like a heavy electron. There are, it is claimed, both positively and negatively charged mesotrons. It is probable that cosmic rays consist of mesotrons, at least those which possess power of deep penetration.

Then, there are *neutrettos*, *negative protons*, and *neutrinos*. The neutretto is supposed to be a particle equal in mass to the mesotron, but electrically neutral. Its position relative to the positive and negative mesotrons is similar to that of the neutron relative to the proton and electron. Through collision with a neutron, it is thought, a neutretto would be transformed into a negative mesotron, and through collision with a proton into a positive mesotron; this, however, is speculative. In fact, there is but slight experimental evidence in favor of the existence of the neutretto. Scientists also postulate the existence of a negative proton on various grounds, but its existence is not certain. The same must be said of the neutrino. If it exists, it

is assumed that its mass is the smallest of all subatomic particles. It is electrically neutral. Extensive experiments are being conducted to prove the existence of these particles, but so far these efforts have not met with much success.

THE PHOTON

The story of the scientific research into the nature of light is one of the most interesting chapters in the history of physics. It dates back to about 1666, when *Newton* succeeded in dividing sunlight into the spectrum. Because of the fact that light travels in straight lines, Newton advocated the theory that light is corpuscular in nature. At the same time *Huygens*, because of the similarity in behavior observed between light and sound, brought forth the view that light is essentially an aether pulse traveling in waves. In 1800 *Thomas Young* proved that light can be diffracted. He also showed that light, like anything that travels in waves, is subject to interference. If light is corpuscular, the meeting of one ray with another should always produce light of greater intensity. If light is a wave formation, the meeting of the crest of one wave with the trough of another should produce a cancellation of both, resulting in a dark band between two light bands where the crests meet. He demonstrated the fact that such interference and mutual cancellation actually occur. The corpuscular theory was doomed, and the undulatory theory of light was triumphant.

As time went on, heat, wireless waves, ultraviolet and infrared rays, X rays, and gamma rays were all explained by the wave theory without any particular difficulty. Their differences consisted merely in differences of wave length and frequency. The aether was their common carrier. All these types of aether waves, as was to be expected, could be subjected to diffraction and interference, and remained uninfluenced by electric and magnetic fields of force. That X rays were a species of light waves was proved conclusively by Laue in 1912. Light can be diffracted either through a prism or through a grating. Man-made gratings cannot be used to diffract X rays, because the spacing between the lines of an artificial grating cannot be made fine enough; the wave length of X rays is too short. Laue conceived the idea of using the natural, molecular spacings of a crystal for a grating. The X rays gave a diffraction pattern. So also did the gamma rays. There could be no doubt, then, that X rays and gamma rays, like light, were *electromagnetic waves*.

However, difficulties began to arise. Light, when it leaves its source, if it is undulatory in character, must spread outward as a spherical wave, growing larger and larger the farther it recedes from the source. Since its energy is distributed uniformly over this entire wave front, it must decrease in strength with the distance from the source. The phenomenon of the *photoelectric effect* disproves this. It was found that light, especially ultraviolet light, ejects electrons from a metal. Experiments were made, from 1900 on, with light on various kinds of metals in such a way that the intensity of the light was changed while the frequency (color) remained constant, and then the frequency changed

while the intensity remained constant. The result was astonishing.

It was found that the amount of electrons drawn out of the metal was entirely and solely *proportional to the specific frequency of the incident light and altogether independent of its intensity*. To produce the photoelectric effect, or emission of electrons under the stimulus of light, each substance requires a critical wave length; the electropositive elements need a longer wave length than the electronegative. Any ray of light that has a wave length longer than the specific wave length required by a substance will not cause electrons to emerge. The alkali metals, potassium, sodium, and caesium, give the photoelectric effect even with visible light; they are strongly electropositive. Others require ultraviolet rays. In all cases it was discovered that the energy of the electrons ejected under the influence of blue light is twice that of those ejected by red light. Using monochromatic light, for instance blue or red, the number of electrons ejected per unit time will be proportional to the light strength. If the light strength is reduced to one half, only one half as many electrons will emerge as under light of unit strength; and if this strength is reduced to one third, only one third as many electrons will be freed from the metal. However, *no matter at what distance the source of this light is placed from the metal, whether at a distance of a foot or of a mile, the energy of the individual electron is always the same*. Now, if light consists essentially of waves, this would be impossible, because the energy of a wave decreases in its effectiveness when the distance from the source is increased. The only

way to explain this remarkable phenomenon is to assume that light is essentially corpuscular in character. Then it can be understood how 'bundles' or 'parcels' of light energy will remain together, while traveling through space, and not lose their striking power on the way. Since their energy is not spread out and weakened through the expanding action of a spherical wave, they retain their full energy from the moment they leave their source until they strike the metal. Each light dart thus carries an amount of energy proportional to its frequency, and it is with this original and undiminished energy that it strikes an atom and ejects electrons.

X rays and gamma rays act exactly as do ultraviolet and ordinary light rays. They must all, then, be considered as being fundamentally *corpuscular* and *atomic* in nature. Such light darts are now called photons.

THE QUANTUM

In 1900 *Max Planck*, through experiments in heat radiation, came to the conclusion that an atom never emits energy continuously, but only intermittently, in definite quantities or parcels. He designated such a definite parcel a quantum. At the time he still considered light to be essentially a wave phenomenon. These quanta of energy are units equal to, or multiples of $h\nu$, in which ν is the frequency of the radiation and h a universal constant the value of which has been determined as 6.55×10^{-27} ergs. This constant is called 'Planck's h .'

At first it was thought that in the photoelectric effect the atoms absorbed energy from the waves of light continuously and gradually, until they had absorbed a quantity equal to $h\nu$; then the energy is emitted as 'quanta' or parcels. This, however, is not the case. A gradual absorption and subsequent emission of energy does not take place; the electrons shoot out of the metal immediately and with full vigor.

As far back as 1905, *Albert Einstein* made the assumption that light traveled in 'light-quanta' equal to $h\nu$, so that atoms absorbed whole quanta or no energy at all. Light was simply discontinuous and discrete under all conditions. Such a quantum of light, on striking an electron, would transmit to it its entire energy in an undiminished condition, and the electron would then be ejected with an energy $h\nu - p$; the work required to remove the electron from the metal is represented by p . At the time, Einstein's assumption seemed arbitrary. Subsequent experiments, however, especially those made during 1912—1914, proved his assumption to be correct. The wave theory could not account for the energy required for the *immediate emission* of electrons, as soon as light strikes the metal. This energy has been computed quite accurately. Sodium, for example, shows the photoelectric effect with the ordinary light of a candle. A candle placed at a distance of 3 meters from sodium has an energy of one erg per square centimeter per second falling on its surface. On an atom, the cross section of which is of the order of 10^{-15} square centimeters, this energy amounts to about 10^{-15} ergs. This amount of energy is insufficient to free an electron, because not more than

one third of the light beam has a wave length short enough to produce the photoelectric effect; the amount of energy which the atom could thus absorb would not be more than $\frac{1}{3} \times 10^{-15}$ ergs per second. An electron, however, is emitted with an energy amounting to 5×10^{-12} ergs. To absorb this amount, the atom of sodium would have to be exposed to the action of the light for more than four hours before it could expel an electron. It is a fact, though, that electrons are expelled from sodium as soon as the candlelight falls upon its surface. It follows, then, that the incident light from the candle must consist of photons which have the necessary *quantum of energy* represented by $h\nu$. It is thus seen that not only the emission, but also the absorption, of energy takes place in quanta. Einstein's assumption has been vindicated: light consists of photons.

WAVES AND PARTICLES

Light has *momentum*. This can be observed in the Wilson expansion chamber. X rays, gamma rays, and cosmic rays, when striking an electron which is free, impel it forward in the direction of their own movement; they act like projectiles.

A. H. Compton proved conclusively in 1923 that photons and free electrons, on colliding, obey the same mechanical laws observed in the encounter of two billiard balls. The photoelectric effect caused by ordinary light and ultraviolet rays shows that photons have momentum. In all elementary processes, therefore, the behavior of aether waves is that of corpuscles or particles. This, however, does not eliminate

the phenomena of *interference and diffraction*, so commonly observed wherever light rays appear in gross quantities. Waves are still associated with light, so that light exhibits the phenomena of *both waves and particles*.

If this double feature of light was a puzzling mystery to physicists, the mystery became more puzzling when it was discovered that electrons, which are undoubtedly corpuscular, also behave like waves. In 1927 Davisson, Germer, and G. P. Thomson, and later Otto Stern and others, sent a stream of electrons through crystal lattices onto photographic plates. To their amazement they obtained diffraction and interference patterns which were similar to those obtained from X rays under the same conditions. But such a phenomenon is characteristic of wave physics. We thus observe the peculiar fact that particles behave like waves, and waves behave like particles.

This is a most disturbing situation. Waves are not particles, and particles are not waves. Are the ultimate components of nature waves or particles? They cannot very well be both at the same time. This much, however, seems certain: Waves and particles are always associated and found together. But why should particles, since they are not waves, show diffraction patterns when shot through the spacings of a crystal? The following suggestion has been offered. Photons of light, in passing through a grating of very fine wires or of a crystal, can be deflected only by the shape of the wire or crystal surface with which they come in contact; since they are much smaller than the space of the grating between the wires or the crystal lattice, this

intervening space can have no influence on their direction. Reversely, if light is but a system of waves passing through the grating, its deflection depends upon the spacing between the wires or crystal lattice, because its wave front, due to the wave length of light, will cut across the entire spacing. Assuming then, that the speeding particles cause waves of aether to pulse in all directions, the aether waves will be deflected by the grating, and the *particles* follow the guidance of the waves through the wire prism or crystal. The concomitance of waves and particles would thus be explained. Further investigation is needed.

Waves always accompany the elementary processes of particles; but this does not mean that the particles are to be identified with the waves. Nature consists ultimately of certain discrete, atomic entities as units: units of matter or mass; units of electrical charge, both positive and negative; units of radiant energy, photons; and units of action, Planck's constant h . When these units act in an individual capacity, they manifest themselves as discrete entities; but when they combine in large quantities, they present continuous processes which exhibit the form of waves.

SUMMARY OF CHAPTER III

Modern science has succeeded in reducing the 92 elements to fewer fundamentally distinct types of matter as their common components.

1. *Electricity*. Electricity, consisting of positive and negative charges, was at first considered to be a fluid. Faraday's study of electrolytes uncovered experimental evidence which showed that electricity must be 'atomic' in character. However, up to about 1900 the 'aether-stress' theory prevailed. The vacuum tube then revealed the existence of *cathode* and canal rays as *material particles of electricity*.

2. *The Electron and Proton*. Cathode rays consist of *electrons*, each of a mass of $0.0008994 \times 10^{-24}$ grams. The canal rays consist of the positive ions of the substance used in the vacuum tube, shorn of electrons. In the case of hydrogen, these ions are called *protons*, and they have a mass of 1.6808×10^{-24} grams. The electrons have a mass of about $1/1845$ of the proton mass. Electrons carry a negative charge, and protons a positive, and each is calculated to be 4.77×10^{-10} electrostatic units. Their mass and charge are constant. Electricity is thus discrete and atomic in character.

3. *Alpha, Beta, and Gamma Rays*. These rays are emitted by radioactive substances. Alpha rays are helium ions with a double positive charge. Beta rays are electrons. Gamma rays are of the nature of X rays, but of shorter wave length.

4. *Cosmic Rays*. They originate in interstellar space, have a penetrating power far exceeding that of gamma rays, involve energies which reach into hundreds of millions of electron volts.

5. *Positrons*. They are material particles equal in mass to electrons, but of positive charge. They originate from cosmic rays and also through the bombardment of various elements with alpha and gamma rays. It is probable that they are at times converted into gamma rays by uniting with electrons. In all probability, they proceed from the nucleus of atoms.

6. *Neutrons*. They are particles of the general mass of protons, but are electrically neutral or uncharged. They possess a high power of penetration. A neutron may be a proton with an electron closely attached, or an unelectrified portion of matter which becomes a proton through the addition of a positron.

7. *Photons*. They are light darts of unit energy. The aether-wave theory of light has been discredited through the *photoelectric effect*, i.e., the emission of electrons from metals under the stimulus of light. The amount of electrons emitted is proportional to the specific frequency of the incident light and independent of its intensity. Bundles or parcels of light remain together in their passage through space without diminishing their energy. Light is, therefore, corpuscular in character. All forms of light, X rays, gamma rays, ultraviolet rays, etc., have the same character.

8. *The Quantum*. A quantum of energy is a unit quantity or parcel of energy absorbed or emitted by an atom. Quanta are units of energy equal to, or multiples of, $h\nu$, in

which ν is the frequency of radiation and h (Planck's constant), a universal constant with a value of 6.55×10^{-27} ergs.

9. *Waves and Particles*. Light exhibits the phenomena of both waves and particles. Electrons, though particles, also give diffraction and interference patterns when shot through crystals; they then act like waves. *Particles thus behave like waves, and waves like particles*. This is the mystery of modern physics.

Nature consists ultimately of certain discrete, *atomic entities*: units of matter; units of electrical charge; units of radiant energy; and units of action.

READINGS

Soddy, Fred., *The Interpretation of the Atom*. Crowther, James Arnold, *Ions, Electrons, and Ionizing Radiations*. Zimmer, Ernst, *The Revolution in Physics*. Millikan, Robert A., *Electrons, Protons, Photons, Neutrons, and Cosmic Rays*.

1 A *coulomb* is the quantity of electricity conveyed in one second by the current produced by an electromotive force of one volt acting in a circuit having a resistance of one ohm — 96,494 coulombs are called a 'faraday.'

2 By the *electrostatic unit of charge* is meant the charge which, when placed on an object which is centimeter apart from a similarly charged object, makes these two objects repel each other with a force of dyne.

3 An *electron volt* is the energy acquired by any particle of unit electronic charge e , for instance by an electron or proton, in traversing a field which has a voltage of one volt.

Chapter 4

THE TRANSMUTATION OF ELEMENTS

FROM A CHEMICAL STANDPOINT, THE ELEMENTS FORM THE ultimate building materials of the universe. All bodies can be reduced to the elements, and they themselves are irreducible. Up to within recent times, it was an axiom among chemists and physicists that each element possessed a distinct individuality which could not be lost or changed. The alchemist's dream of transmuting elements, of changing a base metal into a noble metal, was considered fantastic and utterly impossible of achievement. While it is still impossible to change lead into silver and copper into gold, scientists have been brought face to face with the undeniable fact that *transmutation*, or the change *of one element into another*, actually occurs.

One type of transmutation is a *natural* transmutation, taking place among radioactive elements; the other type is an *artificial* transmutation, effected in the laboratory of the scientist by bombarding elements with certain kinds of rays. Since such elemental changes are of fundamental importance to the cosmologist for a correct understanding of bodies, both types of transmutation will now be discussed.

RADIOACTIVE SUBSTANCES

Radioactive substances are those which, through their own natural powers spontaneously emit alpha, beta, or gamma rays, or combinations of these rays. Radioactivity was discovered in 1896 by *Henri Becquerel*. He thereby put science on the threshold of far-reaching revelations concerning the structure and constitution of elements and atoms.

The radioactive elements are the heaviest of the elements in the periodic table. The first of these to become known were uranium, thorium, polonium, radium, and actinium. They were noted chiefly for their fluorescence, for the power of their rays to affect a photographic plate in the dark, and for the ability of these rays to penetrate apparently solid bodies. These elements soon became the object of intense research, and a new world opened up before the astonished gaze of the investigators. What chiefly interested the scientists in the beginning was the fact that the rays were of a *kind hitherto unknown*, that they were emitted *spontaneously* without any stimulus or energy supplied by outside agencies, and that their emission was *inevitable* in character. A closer study of the radiations revealed three types of rays, and they were named 'alpha,' 'beta,' and 'gamma' rays.

Very early in the history of radioactivity, *Madame Curie* made the generalization that radioactivity is a *unique property of the atom*. It was her contention that the energies manifested by these substances emanated from the interior of the atom, and in consequence of this the

atom itself must undergo a radical change, a chemical transformation, because the atom, which is the seat of radioactivity, cannot remain intact in the process; in other words, the evolution of so much energy from the very heart of the atom necessitates the *disintegration* of the atom. Her generalization, though attacked at the time, proved to be in perfect agreement with the facts as subsequently discovered. Radioactive elements disintegrate and, in doing so, generate new elements.

Once the truth of her conclusion was recognized in its full value, progress was rapid. An intensive study of radioactivity began, tracing the process of disintegration of these elements in all its ramifications. A number of new transmutational elements were discovered arising through disintegration, and one by one the vacant places toward the end of the periodic table were filled. It was also found that there are three main radioactive substances still in existence, from which all others derive their origin. These are: *thorium, uranium, and actinium*.

THE DISPLACEMENT LAW

The transmutation process of radioactive elements is always accompanied by the emission of intense *radiation* of alpha, beta, and gamma rays. Transmutation occurs only when alpha or beta rays are emitted; the emission of gamma rays never occasions the disintegration and consequent transmutation of an element. At first the relationship between radioactive transmutation and the emission of

alpha and beta rays was not understood. After a time, however, this relationship became clear.

In 1911 *Frederick Soddy* showed that the chemical nature of the element resulting from an alpha-ray change is always identical with that of an element *two places preceding* the parent element in the periodic table. This generalization was extended in 1913 by *K. Fajans* and *A. S. Russell* to the beta rays in such a manner that the chemical nature of the element resulting from a beta-ray change is always identical with that of an element *one place following* the parent element in the periodic table. To illustrate. Suppose the element with atomic number 92 emits an alpha particle; the product of this disintegration will have atomic number 90; if the element of atomic number 90 emits a beta particle, the product will have atomic number 91; if 91 emits an alpha particle, the resulting element will be 89; and so forth.

The importance of the discovery of this law can hardly be overestimated. The mere knowledge of the emission of an alpha or beta radiation was of itself sufficient to predict the group qualities of the resulting element, even before the element itself could be completely isolated and studied; and every prediction turned out to be true. It also enabled the scientists to assign the correct place in the periodic table for every element resulting from such radiations. Most important of all, however, was the solution of the mystery of the *essential difference between elements* and the reason of their *atomic number* or place in the periodic table.

RADIATION IN RADIOACTIVE TRANSMUTATION						
STAGES	URANIUM SERIES		THORIUM SERIES		ACTINIUM SERIES	
FIRST STAGE	α				α	
	β		α		β	
	β		β		α	
	α		β		β	
MIDDLE STAGE	α		α		α	
	α		α		α	
	α		α		α	
	α		α		α	
END STAGE	β		β		β	
	α	β	α	β	α	β
	β	α	β	α	β	α
		β				
		β				
		α				

Every alpha particle has a net charge of two units of positive electricity, namely, $+ 2e$. When an atom emits an alpha particle, the total positive charge of the atom is reduced by two units. By that very fact, however, its chemical nature is changed to such a degree that it is identical with the chemical nature of the element (if there be such an element) two places preceding it; its atomic number in the periodic table is thereby reduced by 2. When, however, an atom emits a beta particle, it loses an electron, for the beta particle is nothing but an electron with a unit charge of negative electricity; and in losing a unit charge of negative electricity, the atom acquires a net charge of one unit of positive electricity. The chemical nature of this atom is now identical with that of the element

(if there be such an element) of the next place following it. The conclusion is inevitable that the succession of atomic numbers or places in the periodic table is determined by a *single unit charge of positive electricity*, each element in this progressive list possessing, in the line of increasing weights, one positive charge more than its predecessor. No matter what the atomic weight of an element may be, its chemical *properties*, as represented by the atomic number, depend on its electric *charge*.

Having explained the Law of Displacement, we must now see how the law functions in the disintegration and transmutation of the radio-elements.

COMPARATIVE TRANSMUTATION

Radioactivity is always accompanied by the following events, which show that the changes involve a *real disintegration of the elemental atom*. Only a fraction of the element becomes unstable at any particular time; but this fraction represents a definite proportion of the total number of atoms of that element, and this fraction differs with the different radioactive elements. The expulsion of alpha particles always involves a loss of mass and a change of chemical properties, resulting in a new type of element. The expulsion of beta particles, though producing no change in mass, involves a change at chemical properties, also resulting in a new type of element. These new elements manifest an entirely different behavior to chemical reagents, when compared to the behavior of their parent elements; this is especially clear in the case of the inert

gases, radon, thoron, and actinon. Since there can be no question here of chemical compounds, it is obvious that the progressive loss of mass through the emission of alpha particles and the continuous change of chemical properties through the emission of both alpha and beta particles, resulting in a change of electric charge, must bring about a profound change *in the very atom itself*. The evolution of large amounts of energy in the process bears this out.

Each of the three disintegration series runs its own inevitable course, and no alteration in the chain of events has ever been discovered. No known chemical or physical agency can hasten or retard the process of transmutation. Each series has its peculiarities. Upon closer examination, however, a definite pattern emerges in the three independent series. All follow a remarkably similar line. This becomes evident when we trace the *sequence of alpha and beta radiations* in each series. A glance at the radiation chart shows this clearly. The middle stage is especially noticeable, inasmuch as each series has four alpha radiations in succession. The end of each series is also identical, except that one branch of the uranium series continues with two beta radiations and one alpha radiation. Each branch, however, ends with atomic number 82, that of the element of lead.

The products of the alpha and beta radiations, in so far as they affect the atomic numbers and atomic weights, can be seen in the chart of *comparative radioactive transmutation* (see chart). It will be noted that an alpha emission involves a loss of two atomic numbers and a loss of four units of atomic weight. On the other hand, a beta

emission leaves the atomic weight unchanged, but increases the atomic number by one unit. This results in numerous *isotopes* and *isobars*. Isotopes, though of different weights, are chemically identical, and thus occupy 'the same place' in the periodic table and have the same atomic number. For example, actinium X, mesothorium I, and thorium X are isotopes of radium, atomic number 88; actinon and thoron are isotopes of radon, atomic number 86; radium C, radium E, actinium C, and thorium' C, are isotopes of bismuth, atomic number 83, which is not radioactive at all. Isobars, as the term indicates, have 'the same weight' although they are chemically diverse; hence, they have different atomic numbers and occupy different places in the periodic table. A beta radiation, since it does not change the atomic weight, always gives rise to isobars. For example, uranium X₁, uranium X₂, and uranium II are isobars, with atomic weight 234; uranium Y and protoactinium are isobars, with atomic weight 231; mesothorium I, mesothorium II, and radiothorium are also isobars, with atomic weight 228. If we compare the end products of the three series, we find that the isotopic and isobaric elements are very numerous.

Some of these transmutational elements are so short lived and appear in such minute quantities, that it is almost impossible to determine their atomic weight. For some of them the weights given are not experimentally determined, but are deduced from the type of radiation according to the Law of Displacement.

HELIUM AND RADIOACTIVITY

From the very beginning, since the discovery of the radioactive elements, it had been noticed that helium made its appearance. This led to the conjecture that helium might be a product of radioactive transmutation. The conjecture became practically a certainty when it was found that the alpha particles had the *mass of helium atoms*, but with a *double positive charge*. Compared with the hydrogen atom, the helium atom has an atomic weight of 4, and an alpha particle always has a mass of 4 units of atomic weight. If, then, a helium atom could be shorn of two electrons, it would be an ion with a double positive charge and as such equivalent in every way to an alpha particle. Ramsay had already found helium in uranium and thorium minerals in 1902 it seemed natural to suppose that helium was a disintegration product of these minerals. Experiments were made in 1903 by *Ramsay* and *Soddy* with radium and radon. The results showed beyond doubt that helium was generated through alpha radiation, the spectrum of helium gradually becoming visible as the radon disintegrated. Since that time the transmutation of radio-elements into helium has been observed on many occasions. *Debierne* observed it in connection with actinium, *Mme. Curie* with polonium, *Boitwood* with ionium, *Soddy* and *R. J. Strutt* (Lord Rayleigh) with uranium and thorium. In 1909 *Rutherford* and *Royds* furnished direct proof that the alpha particles emitted by radon are identical with helium.

COMPARATIVE RADIOACTIVE TRANSMUTATION			
(The numbers below the elements are the atomic weights. Underscored names are listed in the Periodic Table.)			
Atomic Number	Uranium Series	Actinium Series	Thorium Series
92	URANIUM (I) (238)	URAN. II (234)	(ACTINO-URANIUM) (235)
91	α URAN. X _{II} (234)	β PROTOACTINIUM (231)	
90	β URANIUM X _I (234)	α URANIUM Y (231)	RADIOACTINIUM (227)
89	α IONIUM (230)	β ACTINIUM (227)	THORIUM (232)
88	α RADIUM (226)	α ACTINIUM X (223)	MESOTHOR. II (228)
87	α	α	α MESOTHOR. I (228)
86	α RADON (222)	α ACTINON (219)	α THORIUM X (224)
85	α	α	α
84	α RADIUM A (218)	α ACTIN. A (215)	α THORIUM A (216)
83	β RAD. C' (214)	β ACTIN. C' (211)	β THORIUM C' (212)

	α RAD. C'' (210)	α ACTIN. C'' (207)	α THORIUM C'' (208)
	β LEAD (210)	β LEAD (207)	β LEAD (208)
	α RAD. D (210)	α LEAD (206)	α LEAD (208)
	β (RAD. F) POLONIUM (210)		

All elements found on the same horizontal level, are *isotopes*. All elements having the same atomic weight, are *isobars*.

Inasmuch as alpha particles are helium ions with a double positive charge, it was a foregone conclusion that under ordinary circumstances they would not long remain in this ionized condition. Lacking two electrons, they would seek to capture stray electrons in their passage, thereby becoming helium ions with a single positive charge or entirely neutral helium atoms. Such is actually the case. Helium itself, of course, is not radioactive; it is a by-product of the disintegration process.

It is one of the oddities of nature that *potassium*, *rubidium*, and *tellurium* are also naturally radioactive. They

spontaneously emit beta rays of a comparatively soft type, but their radioactivity is so feeble that hardly more is known than that it does exist. *Neodymium* and *samarium* are now also classed among the naturally radioactive elements.

ARTIFICIAL DISINTEGRATION

One of the remarkable features of radioactive transmutation is the high velocity and consequent penetrating power of the alpha, beta, and gamma particles, which is far in excess of that ordinarily obtained in a vacuum tube. Voltages of more than a million electron volts are required to effect such speeds. Since the natural disintegration of elements, due to the enormous interatomic energy of the radioactive elements, was an established fact, the question arose among scientists, whether it would be possible to produce an *artificial disintegration* of non-radioactive elements by *bombarding* them with high-speed particles. Nature supplied such projectiles in the alpha particles. It seemed probable that an atom, hit by such a powerful projectile, might be 'smashed' and lose one or the other of its component parts; in that case it should react like a radioactive element and suffer transmutation. Studies of the passage of alpha particles through matter supported this view. Usually these particles will pass through all material substances in a rectilinear course without deflection. Occasionally, however, the Wilson chamber reveals a wide-angle single scattering, which indicates that the alpha particle collided with the massive or nuclear

portion of an atom. The width of the 'angle depends on the mass of the atom struck, whether it be heavier or lighter than, or equal to, the mass of the alpha particle, the results following the ordinary laws of dynamics. In the case of a "head-on" collision there will be no angular deflection, but only a change in velocity depending on the ratio of the masses of the colliding particles and atoms.

Alpha particles of radium C', having a range of 7 centimeters, were shot through hydrogen; after a collision, the hydrogen ion attained a range of 28 centimeters. Nitrogen gas, under bombardment of alpha rays, yielded *hydrogen ions* with a range of 40 centimeters, a range considerably longer than that yielded by hydrogen gas itself. This fact proved that these excessively long-range hydrogen ions could not have their origin in any stray hydrogen atoms mixed with nitrogen; they were *protons* (hydrogen ions) knocked out of nitrogen atoms; their longer range being due to a larger evolution of energy on the part of the nitrogen atoms through collision with alpha particles. Had these protons been the result of a collision with stray hydrogen atoms, their range would not have exceeded 27 centimeters. Thus, it was experimentally demonstrated that *nitrogen*, a nonradioactive element, can be made to *disintegrate* under bombardment by alpha rays.

This disintegration of the nitrogen atom, effected by *Rutherford* in 1919, also brought a *transmutation* in its train. It produced *hydrogen* (proton) and an isotope of *oxygen* of atomic weight 17. In order to illustrate these and similar transmutations graphically, symbols and equations are used, giving the symbol of the elements involved, their

atomic number and atomic weight; the atomic numbers are placed as subscripts to the symbols, and the atomic weights as superscripts. The atomic numbers on both sides of the equation must result in equal sums, and so also must the atomic weights. Applying this formula to the Rutherford nitrogen transmutation, we obtain the following equation:

This equation reads: an alpha particle or helium ion (atomic number 2, atomic weight 4) collides with a nitrogen atom (atomic number 7, atomic weight 14). The alpha particle is stopped and captured by the nucleus of the nitrogen atom, merging with it; at the same time a proton or hydrogen ion (atomic number 1, atomic weight 1) is expelled, reducing the atomic weight of nitrogen by one unit (N^{13}); the four mass units contained in the alpha particle, all of which possess individually the mass of protons, unite with the mass of the nitrogen atom to form oxygen of atomic weight 17. *Oxygen* and *hydrogen* are thus seen to be a transmutational product of the bombardment of *nitrogen* by *alpha* particles. The equation of atomic numbers yields the same sum of ($2 + 7 = 8 + 1$) and the equation of atomic weights equals the same sum of 18 ($4 + 14 = 17 + 1$) The difference between this kind of disintegration and that of the radio-elements is apparent. Radio-elements disintegrate spontaneously in a natural process, through the evolution of inter-atomic energies. This internal process terminates in the emission of alpha and beta rays, and sometimes gamma rays, in such a

manner that there is a gradual loss of atomic mass in definite stages and proportions throughout the entire course of disintegration. In an artificial disintegration the process of transmutation is effected through a disruption of the elemental atom by means of an external agency of great force, and this takes place, in a general sense, with an equilibrium of mass.

Rutherford's method of bombarding nitrogen with alpha particles was applied successfully to a number of light elements, all yielding hydrogen particles. It is a curious fact that the odd numbered elements are subject to disintegration more readily than the even-numbered elements. The latter are far more stable than the former and constitute about 87 per cent of all the elements found in the earth's crust, although there are, of course, as many odd-numbered elements as there are even-numbered. Bombardment by alpha particles shows that odd-numbered elements tend to become even-numbered elements. The explanation seems simple enough. In such a bombardment the odd-numbered element loses a hydrogen particle or proton of unit charge; this makes it even-numbered, and it remains in this state if the bombarding alpha particle is not absorbed. If the alpha particle is absorbed, the element is still even-numbered, because the alpha particle has a positive charge of two. While it seems certain, or at least very probable, that all light elements emit hydrogen particles under bombardment, there is no doubt that the odd-numbered elements up to potassium suffer a definite disintegration, some of them expelling hydrogen particles of long range. The H-particles (i.e., hydrogen particles) of

aluminum, for example, have a range of 90 centimeters in air, manifesting a release of considerable energy within the aluminum atom.

TYPES OF ARTIFICIAL TRANSMUTATION

Although alpha particles were very suitable for bombardment purposes, their heavy mass and double positive charge formed a drawback. Scientists began to look about for new projectiles and new methods. However, not until they were able to construct transformers capable of giving electric currents with potential differences amounting to a million or more volts, could they hope for great success along these lines. This has been accomplished in the last decade, especially in the cyclotron of *Lawrence* and *Livingston*, and in the electrostatic generators of *Van de Graaf* and of *Tuве*, *Hafstad*, and *Dahi*, both producing voltages that run into the millions. The cyclotron, for instance, expels particles with a kinetic energy of 5.8 million electron volts. The results have been truly remarkable.

Crocker and *Walton*, in 1932, using a high-voltage discharge tube, bombarded lithium with hydrogen protons and obtained helium nuclei (alpha particles). The equation is ${}_1\text{H}^1 + {}_3\text{Li}^7 \rightarrow {}_2\text{He}^4 + {}_2\text{He}^4$. *Rutherford* bombarded lithium with deuterons (nuclei of heavy hydrogen, H^2), and also obtained two helium atoms. In this case, however, the effect must have been produced with the lithium isotope Li^6 , so that the equation is: ${}_1\text{H}^2 + {}_3\text{Li}^6 \rightarrow {}_2\text{He}^4 + {}_2\text{He}^4$. When

hydrogen is bombarded with deuterons, very heavy hydrogen, H^3 , is produced.

When deuterons bombard deuterons, they result in a proton and in a H^3 hydrogen isotope, according to the equation: ${}_1H^2 + {}_1H^2 \rightarrow {}_2H^3 + {}_1H^1$. Deuterons have a mass of 2; they consist of 2 proton masses. Since, however, they possess a single positive charge, it is evident that each deuteron must consist of 1 proton without an electron and 1 proton with an electron. The proton with an electron is a neutron. When, therefore, deuterons are used to bombard deuterons, it should be possible to obtain a *neutron* as the product of transmutation. The equation would be: ${}_1H^2 + {}_1H^2 \rightarrow {}_2H^2 + {}_0n^1$; the neutron would have a mass of one, but a zero charge (${}_0n^1$). Such is the case. In this way neutrons are obtained and can be used as projectiles. They have the great advantage of being uncharged. This gives them an excellent chance of penetrating into the core of the atom, passing through the 'electrical barrier' surrounding the core or nucleus, because they are neither repelled nor attracted, due to their electroneutrality.

One of the most peculiar transmutations occurs when nitrogen is bombarded with deuterons. The reaction is as follows: ${}_1H^2 + {}_7N^{14} \rightarrow {}_8O^{15} + {}_0n^1$. Not only is a neutron formed, but also an isotope of *oxygen with a mass of 15* (O^{15}). So far as is known, this isotope does not occur in nature; it is the direct result of man's ingenuity. Nor is this all. Far more remarkable is the fact that, after the bombardment with deuterons has ceased, 'induced radioactivity' sets in as a delayed action, causing positrons to emerge, the emissions lasting sometimes for hours after

the original transmutation. The reaction then takes the following course:

The positron (e^+) has a positive charge, but no (appreciable) mass. Through a process of spontaneous radioactivity, then, the unstable isotope of oxygen (O^{15}) reverts to an isotope of nitrogen of atomic mass 15 (N^{15}) by emitting *positrons*. This is unique. The natural radioelements emit negative electrons (beta particles), but never positrons.

Neutrons are now used extensively as projectiles in artificial disintegration and transmutation, and they have proved to be a most powerful weapon of attack in the hands of scientific investigators. Here is an example of transmutation through bombardment with neutron particles: ${}_0\text{n}^1 + {}_7\text{N}^{14} \rightarrow {}_5\text{B}^{11} + {}_2\text{H}^4$. In this instance nitrogen was changed to boron and helium (alpha particle). The reverse reaction to this also occurs, and then we have: ${}_2\text{H}^4 + {}_5\text{B}^{11} \rightarrow {}_7\text{N}^{14} + {}_0\text{n}^1$. An interesting case is that of 'radio-sodium,' where sodium simply captures the neutron and absorbs it: ${}_0\text{n}^1 + {}_{11}\text{Na}^{23} \rightarrow {}_{11}\text{Na}^{24}$. A different reaction, but with the formation of 'radio-sodium' as a result, has been obtained by bombarding sodium with deuterons:

${}_1\text{H}^2 + {}_{11}\text{Na}^{23} \rightarrow {}_{11}\text{Na}^{24} + {}_1\text{H}^1$. Sodium, when bombarded with deuterons, emits neutrons, protons, and alpha particles, and it also becomes radioactive; *Lawrence, Livingston*, and others, have proved this. Fermi has

obtained radioactive sodium from aluminum by bombarding it with neutrons, according to the formula: $_{13}\text{Al}^{27} + _0\text{n}^1 \rightarrow _{11}\text{Na}^{24} + _2\text{He}^4$. Many elements become radioactive through bombardment by neutrons, about 50 being listed by Fermi between fluorine and uranium.

Fermi, Amaldi, and their associates have put forth the claim that they have succeeded in producing an element heavier than uranium, by bombarding uranium with neutrons. The reaction is given as follows:

This would be element 93. The fact seems fairly well established. A number of Japanese scientists claim to have obtained element through bombardment of uranium with fast neutrons. Even element 95, it is claimed, has been obtained.

All in all, more than 60 elements have now been successfully transmuted by means of neutron bombardment. This is a truly phenomenal achievement, and the end is not in sight. One thing, however, seems quite certain: *it is impossible to form heavy atoms out of hydrogen*. If this is true, then the primordial element or protyle is not hydrogen.

TRANSMUTATION OF MASS AND ENERGY

Many scientists of repute, deeply versed in the physics of the natural and artificial transmutation of elements, are

strongly convinced that in some reactions a *transformation of mass into energy, and of energy into mass*, takes place. This is a most daring hypothesis, but it is based on what appears to be fairly good evidence.

It will be remembered from foregoing sections of this chapter, that the lithium isotope of atomic weight 7 (${}_3\text{Li}^7$), when bombarded by protons (${}_1\text{H}^1$) gives rise to two helium nuclei or alpha particles (${}_2\text{H}^4$), according to the formula: ${}_1\text{H}^1 + {}_3\text{Li}^7 \rightarrow {}_2\text{H}^4 + {}_2\text{H}^4$. In a similar manner, when lithium of atomic weight 6 (${}_3\text{Li}^6$) is bombarded with deuterons (${}_1\text{H}^2$), it also gives rise to two helium nuclei or alpha particles; the formula in this case is: ${}_1\text{H}^2 + {}_3\text{Li}^6 \rightarrow {}_2\text{He}^4 + {}_2\text{He}^4$. The equation in both instances seems perfectly balanced; the atomic numbers add up to 4 on both sides of the equation, and the atomic weights or masses to 8.

These mass numbers, however, are only rough approximations, because they are given in whole numbers or integers. This was done for the sake of convenience. In reality, the mass numbers are *integers with fractions*, and when these more exact numbers are added together on both sides of the equation the *sums are not balanced*. Taking these exact numbers in the above-mentioned equations, this fact becomes apparent. The first formula then reads:

The mass numbers of the hydrogen proton and the lithium atom give the sum of 8.023, while the mass numbers of the two alpha particles or helium nuclei amount to 8.004;

this is a difference of 0.019 mass units in the equation, and this amount seems to be lost. Similarly, there is a lack of balance in the second equation:

On the left side of this equation we have the same 8.028, and on the right, after the transmutation, 8.004; here there is a difference of 0.024 mass units. What has happened? Provided the original mass numbers are correct, mass seems definitely to have *vanished*. If true, either the principle of the Conservation of Mass does not hold, or this mass must have been transmitted into something else. But into what could mass be converted?

Scientists claim that this loss of mass is due to the conversion of mass into energy. The mass of a body increases when its speed is increased. The mass numbers in the formulas represent the masses of these bodies at *rest*. Before the actual bombardment, the lithium atoms are 'at rest'; the masses on the left-hand side of the equation are, therefore, their 'rest masses. Due to the bombardment and the subsequent transmutation of lithium into helium nuclei, these helium nuclei acquire considerable kinetic energies; this is seen from the long tracks they make in the Wilson chamber. These energies have been computed. In the first of the formulas mentioned above, the energy of the nuclei has been calculated to be about 17 million volts, and for the second about 23 million volts. These energies must be added to the 'rest energies' locked in the 'rest masses of the lithium atom. It is fairly obvious that these kinetic

energies must be derived from the 'rest energies' of the lithium atom and not from the bombarding protons and deuterons, because the latter have energies which are at the most only one twentieth to one fortieth of the energies displayed by the helium nuclei. If, then, it is admissible to assume that mass can be transmuted into energy, the expenditure of energy on the part of the helium nuclei would account for their loss of mass. Is this hypothesis admissible? Can we find any experimental evidence to support this hypothesis? It would seem so.

It has been observed that photons are capable of effecting transmutations. If we designate the photon by the letter 'L' the bombardment of deuterons by photons results in the equation: $L + {}_1\text{H}^2 \rightarrow {}_1\text{H}^1 + {}_0\text{n}^1$. The deuteron disintegrates into a proton and a neutron, and the photon itself disappears. The photons used were gamma rays of a radioelement, and they possessed an energy of 2.6 million electron volts and a corresponding mass of 0.003. Inserting this mass of the photon in the equation, we obtain the following quantities: $L^{0.003} + {}_1\text{H}^{2.014} \rightarrow {}_1\text{H}^{1.009} + {}_0\text{n}^{1.009}$. The masses of the proton and the neutron add up to 2.017, while the mass of the deuteron, from which they originate, amounts to only 2.014. Since the parts cannot make a sum greater than the whole, the conclusion to be drawn from this transmutation is that the energy of the photon has been converted into mass, thus balancing the equation. In other words, when a proton and a neutron unite to form a deuteron, they lose 0.003 units of mass or 2.6 million electron volts of energy; and it takes this same amount of energy in absorption to separate them and to give to each

its original rest mass. If this is true, it explains why the atomic masses of the elements are not exact multiples of hydrogen as a standard, and it also explains why hydrogen has a mass larger than one-sixteenth of oxygen: protons and neutrons, in forming the atoms of elements, change in their energy content and therefore also in their mass.

A more direct proof of this type of transmutation is found in the disintegration of photons in pairs of electrons and positrons. The photon used has an energy of 2.6 million electron volts, while the total energy of the electron and positron is one million volts (500,000 electron volts for each), with an excess kinetic energy of 1.6 million volts to account for their speed and range after formation. This process has been observed and photographed by I. Curie and F. Joliot in a Wilson chamber. The photon itself leaves no track in the chamber, because it is uncharged; the electron and the positron, however, emerge from the same point and leave visible tracks enabling the investigators to compute their energies. Besides instances of this kind, cosmic rays produce veritable showers of pairs of electrons and positrons, thus lending valuable support to the interpretation placed by scientists upon this experimental fact.

Many scientists are, therefore, convinced that energy (light) can be, and actually is, converted into mass. Reversely, then, mass should also be transmutable into energy; and they see evidence of this in the loss of mass in the transmutation of elements, when these elements are bombarded by various kinds of particles.

One must not overlook the fact, however, that all this is *interpretation* of fact, and as such speculative. Then, too, mass numbers are *approximations*, not absolute quantities, and a different interpretation might possibly explain the facts just as well. The evidence is not conclusive.

CONSERVATION OF MASS AND ENERGY

If mass can be converted into energy and energy into mass, as outlined above, it is obvious that the principle of the Conservation of Mass and the principle of the Conservation of Energy will no longer stand in their old form. The total amount of mass in the universe will not always remain the same, nor will the total amount of energy remain the same. However, the total amount of mass plus energy would never change, even when mass is converted into energy and energy into mass. In consequence, many scientists, especially those following Einstein, merge the two principles into the one, fundamental principle of the Conservation of Mass-Energy. Other scientists, however, are inclined to be more cautious and conservative in this extreme simplification of nature and maintain mass and energy as irreducible, ultimate units of the physical world.

Philosophically, the conversion of mass and energy in a reversible reaction involves a most serious difficulty. Mass is the result of *matter*. Energy is not matter, but a *quality* of material bodies. Since photons are considered to be a form of pure energy, they should be conceived as devoid of matter. The conversion of energy into mass would thus

involve the *transformation of a quality into a substance*, namely into matter. This cannot be admitted.

Granting all the experimental facts, is it necessary to assume that the photon is 'pure energy'? It would seem not. Might not the photon have a *material carrier*, a material support of some kind? Physicists, of course, usually state that photons have *no mass*. This must not be taken too literally. They also state that electrons and positrons have no mass. What they mean is that this mass is *negligible*, because it is so small compared to that of a proton (1/1845). The electron is a *material particle* of definite mass. Like the electrons, photons exert pressure, have force of impact, disrupt atoms, and give acceleration to particles. As regards *mass*, they are of the order of electrons and positrons. Why, then, should it be necessary to assume that they are 'grains of pure energy' and not rather 'grains of quantified matter,' as Lucien Matte calls them?¹ He points out the fact that 'mass' and 'matter' are not identical concepts and that photons might very well be 'material' particles ('substances' in the philosophic sense) without having 'mass' (in the scientific sense). He offers the further suggestion that photons, under certain conditions, split into electrons and positrons. According to this view, electrons and positrons unite to form photons, and this would explain why photons are uncharged electrically and why in certain reactions, pairs of electrons and positrons appear. This opinion is, of course, speculative; but it seems plausible and it has the advantage that it evades the necessity of postulating a creation and annihilation of matter or energy or both.

The one great fact which has been established through natural and artificial transmutation is this: *The elements are not immutable*, and their change is effected through the loss or gain of subatomic particles, such as electrons, protons, neutrons, and alpha particles. The elements consist, therefore, of *atoms composed of subatomic particles* united in some sort of *structure*. Details of the structure of the atom, as conceived by the scientists, will be outlined in the next chapter.

SUMMARY OF CHAPTER IV

The transmutation of elements, or the change of one element into another, is a fact. Such transmutations are either *natural* or *artificial*.

1. *Radioactive substances*. They emit alpha, beta, and gamma rays spontaneously. Radioactivity is a unique property of the *atom*, involving the disintegration of the atom in the process. The three main radioactive substances are thorium, uranium, and actinium.

2. *The Displacement Law*. According to the Displacement Law, whenever an *alpha* change takes place, the resulting element has a chemical nature identical with that of an element two places preceding the parent element in the periodic table. Whenever a *beta* change takes place, the resulting element has a chemical nature identical with that of an element one place following the parent element in the periodic table. In an alpha change the positive charge of the atom is reduced by two units, and in a beta change the positive charge is increased by one unit. Hence, the chemical properties of elements and their place in the periodic table is determined by the *positive charge* of the elemental atom.

3. *Radioactive Disintegration*. *Thorium*, *uranium*, and *actinium* disintegrate into various new elements through alpha and beta ray emissions. Their courses are similar, though they differ in details. In their middle stages all are characterized by four successive alpha changes. All end in *radio-lead* of atomic number 82. An alpha particle, when

emitted, involves a loss of four units of atomic mass or weight, and two places of atomic number. A beta particle, when emitted, involves no loss of atomic mass, because it is an electron; it increases the positive charge by one, because it involves a loss of a unit negative charge.

4. *Helium and Radioactivity.* Alpha particles are helium ions of atomic mass 4 and + 2 charge. Helium is thus a byproduct of radioactive disintegration.

5. *Artificial transmutation.* It is effected through the bombardment of elements by subatomic particles, such as alpha particles, neutrons, protons, and also by bombardment with deuterons (heavy hydrogen ions). In some of these reactions positrons are emitted as a product. It is claimed that element 93 is also produced. Many elements, after bombardment, become radioactive.

6. *Transmutation of Mass and Energy.* Many scientists are convinced that some artificial transmutations involve a conversion of *mass into energy* and of *energy into mass*. Others disagree with this conclusion. Philosophically, this would necessitate the assumption that a quality (energy) could be converted into a substance (mass, matter) and a substance into a quality; this seems impossible. A photon, which is the energy in question, might possibly consist of quantified matter composed of an electron and a positron.

Chapter 5

THE STRUCTURE OF MATTER

IN THEIR LAST ANALYSIS ALL BODIES, COMPOUNDS AND elements, are composed of atoms. The *atom* is considered to be the *fundamental unit* of all chemical substances. It is of vital interest to the cosmologist, therefore, to know what reputable scientists have to say concerning the structure of matter and particularly of the atom, in so far as the conservative interpretation of true facts warrants definite conclusions. It is outside the scope of this book to adduce all the evidential facts, argumentations, and calculations which scientists advance in support of their views; an outline of the general results must suffice.

THE STRUCTURAL ATOM

Formerly it was thought that atoms were solid bodies of uniform matter. This was the theory of *Dalton*. Modern physics has disproved this. *Atoms are complex entities*, consisting of negatively and positively charged particles. How do these particles build up the atom?

It is now accepted as certain that all atoms possess a *structure* which is characteristic for each element. This

conclusion is drawn from the periodic recurrence of definite group properties among the elements. The Zero or 0 elements are the natural points of division for these properties, and these Zero elements (helium, neon, argon, krypton, xenon, and radon) appear in the sequence of elements according to a distinctly mathematical plan. A fortuitous aggregation of electrons and positively charged masses could never account for the periodic recurrence of such definite properties between one Zero element and the next. The elements become progressively more massive as they proceed from hydrogen to uranium. Mass alone, however, cannot be the deciding factor of these sequences of group properties. For one thing, the masses (or weights) progress uniformly in a straight line, while the properties of the elements reappear between the Zero elements in cycles. Then, a difference of mass does not always entail a difference in elemental properties, as can be seen in the case of isotopes. Furthermore, the masses of the various elements overlap, and this could not happen if the masses decided the nature of the element. Finally, in a number of instances elements of higher atomic mass (weight) must be placed in the list before one of lower atomic mass, because of their chemical and physical group qualities; this is a plain indication that the mere number of particles constituting the atom does not decide the properties of an element. Yet it is the *properties* which distinguish one element from another. Since, then, the mere numerical increase of constituent particles does not account for the characteristic properties of the elements, it is legitimately concluded that the nature of the element is determined by the

configuration and arrangement of the component parts within the atom. In other words, *atoms have structure*. This structure must determine the existence of the various *kinds* of elements; and the *periodic similarity* of this structure must be the reason for the periodic cycles of properties which appear from one Zero element to another. This seems to be a logical explanation of the facts.

While it is fairly obvious that the atom must possess internal structure, this does not tell us much about what *sort of structure* exists in the atoms of the elements. The correct interpretation of this structure must explain the 'differences' which mark off one element from another and also the 'periodic similarities' which recur at definite intervals. Radioactivity shows that the elements differ among themselves because of a difference in their *positive* charges. When an alpha particle (with a $+2e$ charge) is emitted, the new element loses two places in the Table of Elements; when a beta particle (an electron with $-1e$) is emitted, the new element advances one place, because the loss of $-1e$ is equivalent to the gain of $+1e$. The loss of an electron, however, does not always bring about the birth of a new element. When elements are ionized,' they lose (or gain) one or more electrons; yet these elements retain their specific character and do not change into new elements. For example, hydrogen and helium become ionized by losing electrons, but they remain hydrogen and helium; the same is true of the other elements. Then why should the emission of an electron (beta particle) in radioactivity produce a new element? Evidently, the *position* and *function* of the electrons in the atoms are *not of the same*

kind in all ways, but depend on the internal structure of the atoms.

This much is certain: the electrons carry the negative charges of the atom, and the heavy mass carries the positive charges. By stripping an atom of one or more electrons, it becomes ionized (a positive ion); by adding one or more electrons, it also becomes ionized (a negative ion). There is, however, a definite *limit* to the number of electrons which can be taken from, or added to, an atom. It is obvious, therefore, that some electrons must be more closely united than others to the heavy, massive, positively charged portion of the atom, so that they always remain united. Ordinary ionization, then, occurs through the loss or gain of these 'loosely bound' electrons, leaving the 'elemental' character of the atom intact; in radio-activity, on the other hand, the emission of an electron (beta particle) must mean the loss of a 'closely bound' electron from the massive part of the atom. If all electrons were bound in the same manner to the general mass of the atom, having the same position and function, this great difference in the behavior of the atom in ionization and radioactivity is inexplicable. It is, therefore, assumed that the electrons taking part in the process of ionization must be *outside* the *massive part* and at some distance away: such electrons could be lost or gained without disturbing the 'elemental' character of the massive part. The loss or gain, however, of an electron in the massive part, since the latter determines the atom in so far as it is an element, would involve the disintegration and transmutation of the element itself, as observed in radioactivity. This means that the atom is

essentially a *nuclear atom*, with the heavy, positively charged portion as the central part or 'nucleus,' and with at least some of the electrons as having positions at some distance from the nucleus. It is thus easily understood how an alpha particle or other projectile, passing near an atom, can separate such outlying electrons from the nuclear mass, ionizing the atom but leaving it essentially intact.

From the relatively very few instances of collisions between alpha projectiles and atoms in the passage of the alphas through a foil, and also from the angle of scattering which some of these alpha particles suffered, *Rutherford* (1912—13) deduced that the atom could not be a compact mass, but a nuclear central mass of net positive charge with a field of negative electrons stationed at relatively great distances from it. This is the accepted view now, and it seems to agree admirably with all the correlated facts.

Hydrogen is the simplest of all elements. Whether disrupted in the discharge tube or through bombardment, the hydrogen atom has never been known to yield more than one electron of unit negative charge and one proton of unit positive charge. The proton, or nucleus, constitutes the mass of the hydrogen atom and apparently cannot be broken up in any way into simpler and smaller parts. It is, therefore, concluded that the hydrogen atom consists of these two parts only — one electron and one proton; together they form the neutral hydrogen atom. *Deuterium*, which is an isotope of hydrogen (${}_1\text{H}^2$), has double the mass of ordinary hydrogen. When a deuteron is bombarded with a photon, it yields a proton and a neutron ($\text{L} + {}_1\text{H}^2 \rightarrow {}_1\text{H}^1 + {}_0\text{n}^1$), each of which has the mass of an ordinary hydrogen

atom. To all appearances, the proton loses its electron, but the neutron retains the electron so that it remains electrically neutral. So far as is known, neutrons never lose their electron. This bears out the view that electrons may be either 'loosely bound' or 'closely bound' to its nucleus. Since the mass of the neutron is slightly less than that of the hydrogen atom, it is often called a 'collapsed hydrogen atom.'

Helium, the element next to hydrogen, has an atomic mass of 4. If it consists of 4 protons, it must also have 4 electrons, because it is electrically neutral in the normal state. Alpha particles are helium ions with a net positive charge of $+ 2e$. Two electrons, therefore, are missing. But a helium nucleus never loses more than 2 electrons. One must, then, conclude that 2 of its electrons are at a distance from the nucleus and can be lost, while the remaining 2 electrons are very closely united to the nucleus and cannot be detached. Its atomic number is, therefore, 2; and its atomic weight is 4. Furthermore, helium is an inert gas, with no tendency to unite with other elements to form compounds; it is a balanced, stable atom. On the other hand, hydrogen is a very active element, possessing a strong tendency to combine with other elements. Why the difference between hydrogen and helium? If the view of the nuclear atom is correct, this is to be expected. The hydrogen atom has a lone electron in its outer field, while the helium atom has 2 electrons in the nucleus and 2 in its outer field. The hydrogen atom is obviously unbalanced, while the helium atom is balanced. The model for both atoms is conceived to be as follows:

The diagram illustrates graphically the balanced, symmetrical state of the helium atom. It is a naturally 'self-satisfied' atom, with all its forces equalized. Such an atom will have no tendency to lose or accept electrons; it will be chemically inert. Through outside force it may be compelled to give up one or both of its outer electrons, and then it will be 'ionized' with a single or double positive charge. Alpha particles, as we know, are helium ions with a double positive charge; they always, however, tend to pick up stray electrons so as to balance the excess positive charge and thereby become electrically neutral and normal again. Since deuterium (heavy hydrogen) consists of a nucleus containing a proton and a neutron, it is highly probable that the helium nucleus consists of two neutrons and two protons.

The facts just given explain the differences between *atomic number* and *atomic weight*, as manifested in the Periodic Table. The net positive charge of the nucleus, after deducting the negative charges of the extranuclear electrons, gives the atomic number. Hydrogen has a net positive charge of 1 on its nucleus; it therefore has atomic number 1. Helium has a net positive charge of 2 on its nucleus, and it has atomic number 2. We arrive at the same atomic number by counting the number of electrons in the

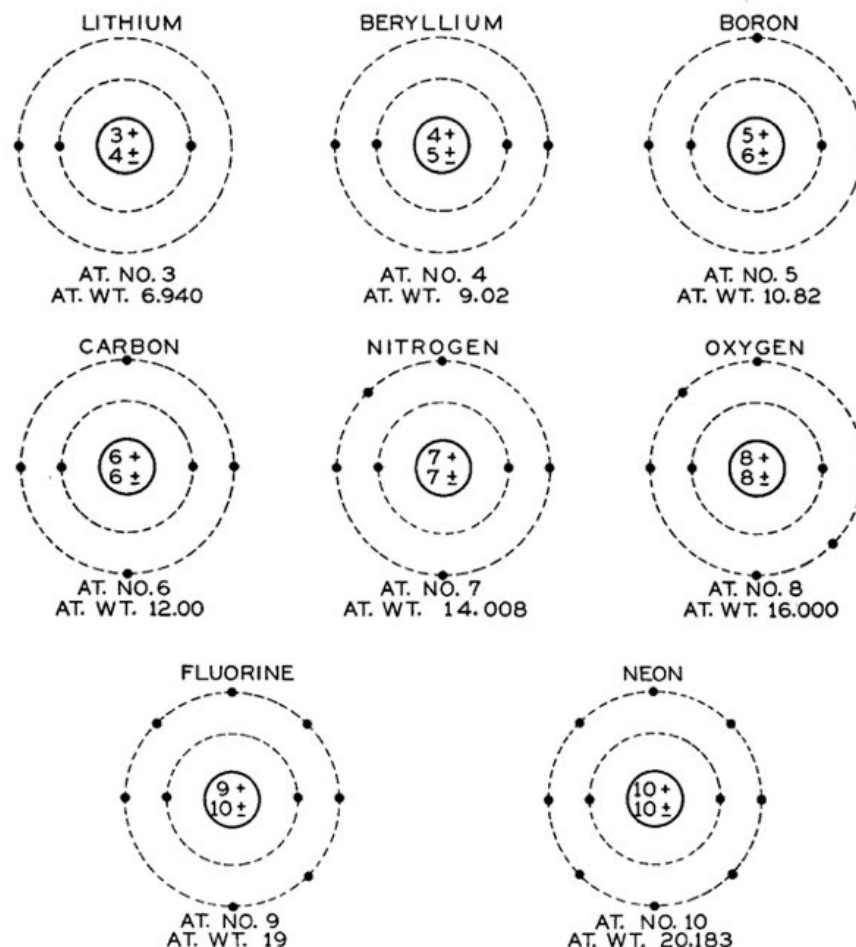

outer field; for hydrogen it is 1, and for helium 2. The character of the atom *as an element* is thus determined by the net positive charge of the nucleus. When the number of outer electrons is increased or diminished, it is a case of *ionization*; but when the nuclear charge is changed, through the loss or gain either of neutrons and protons or electrons (for example, alpha or beta particles) it is a case of the *transmutation* of an element. When a neutron or a number of neutrons (protons and electrons) are added to the nucleus, the mass is increased, but the net positive charge remains the same; we then have *isotopes*. When two atoms have the same mass, but one contains more nuclear electrons (beta particles) than the other, their net positive charge is different and they are also chemically diverse as elements; we then have *isobars*. It is thus seen that some of the most important phenomena of atomic physics receive a logical explanation from this theory of the 'nuclear' atom.

ELECTRONIC SHELLS

Let us now consider the *first short series* of elements between helium and the next inert gas, neon. There are seven members, lithium, beryllium, boron, carbon, nitrogen, oxygen, and fluorine. The properties change gradually from metallic to acidic and from electropositive to electronegative, as we proceed from lithium to fluorine. Neon, like helium, is again an inert element, with atomic number 10 and atomic weight 20. It will be noted that the difference between helium and neon is 8 places, so far as atomic numbers are concerned, and 16 units of mass, so far

as atomic weight is concerned; this alone would indicate that neon also must possess a stable, balanced, symmetrical structure like that of helium. The intermediate elements should possess a structure which leads in a gradual development toward neon. The structure of the atom, as indicated in hydrogen and helium, can be followed through in this series.

When *lithium* is ionized, it has a single excess charge of positive electricity; it becomes electropositive. But it never (or at most very seldom) loses more than one electron, although its nuclear net positive charge must be 3 units, since it has atomic number 3. Why should it lose only 1 electron, when there are 3 in the outer field? It is assumed that the 'helium arrangement' of 2 electrons, which represents a balanced system, is retained in the lithium atom, and the third electron is farther away from the nucleus. That is why, when ionized, lithium loses only this single electron. *Beryllium* has 2 such electrons; *boron*, 3; *carbon*, 4; *nitrogen*, 5; *oxygen*, 6; *fluorine*, 7; and *neon*, 8. In other words, helium is a balanced atomic system with 2 electrons in its outer ring, while neon needs 8 electrons in its second ring or 'shell' in order to be a balanced, symmetrical atom similar to helium. These atoms would then be built up as follows:

These models show how every atom in this series retains the helium configuration ('ring' or 'shell') and builds up a second shell, characteristic of this series, outside the helium shell. When the *octet* of electrons is completed, we have neon, a stable, inactive gas similar to helium; it is balanced and symmetrical, with all its internal forces equalized. The other elements are partly unbalanced and therefore tend to give or take electrons, so as to complete the octet system and thereby become *stable compounds*. Oxygen, for example, lacks 2 electrons in its second shell to complete the octet; it therefore readily unites with 2 atoms of

hydrogen (each of which has an electron) to form the stable compound water (H_2O). Lithium combines readily with fluorine; lithium gives its extra electron and fluorine adds it to its own 7, and the outer shell is filled, forming a stable compound. And so with other elements.

By an *electronic shell* physicists understand a definite field or region surrounding the atomic nucleus, in which the extranuclear electrons are located. These shells are designated by the letters K, L, M, N, etc. The helium shell, i.e., the one next to the nucleus, is the K shell. The one next to this is the L or neon shell. This is followed by the M or argon shell.

Between neon and argon we have the *second short series* of eight elements. Their properties are very similar to those of the first short series. Argon has atomic number 18 and atomic weight 39.944. Argon should, therefore, have a K shell with 2 electrons, an L shell with 8 and an M shell with 8 electrons completing another octet in this M shell, thereby having a stable, balanced, symmetrical atomic structure; it is, as we know, an inactive element like helium and neon. Sodium, according to the nuclear theory, has 1 electron in its M shell; magnesium, 2; aluminum, 3; silicon, 4; phosphorus, 5; sulphur, 6; and chlorine, 7. Their chemical activity is governed by the number of electrons they can give or take.

The *first long series* from argon to krypton has 18 elements. This indicates one of two things: either the N shell of krypton contains 18 electrons, or the N shell has again an octet and the remaining 10 are used to increase the number of electrons in the M shell. Physicists, generally

speaking, accept the latter view. They do this because of the chemical character of the 'interpolated' or 'transitional' elements found in this series. Certain phenomena of energy quanta, optical spectra, and X rays are of such a nature that physicists are convinced that different energy levels exist within each shell. The larger shells contain more energy levels than smaller shells and thus take on more electrons into these levels as the number of elements increase between one inert gas and the next. This would account for the close relationship of the transitional elements, of which the 'rare earths' beginning with lanthanum are a classic example. Thus, the K shell is assumed to have 1 level (10); the L shell, 2(20 and 21); the M shell, 3(30, 31, and 32); the N shell, 4(40, 42, 43, and 42); the O shell, 3(50, 51, and 52); the P shell, 2(60 and 61); the Q shell, 1(70).

Disregarding the distribution of electrons within the energy levels of the single shells, and taking each shell as a unit, the following table shows the results of this speculative arrangement of electrons in the various shells of the atoms of each element.

[chart is too intricate to reproduce and is outdated]

REVOLVING AND SPINNING ELECTRONS

The atom, if the nuclear theory is correct, has a very complicated structure. This structure becomes still more complicated with the assumption that the extranuclear electrons are not stationary but *revolve in orbits* around the nucleus and also have a spin.

Extranuclear electrons, physicists point out, cannot be stationary. An electromagnetic *attraction* exists between the positively charged nucleus and these negatively charged electrons. If stationary, these electrons could not remain at a distance from the nucleus, but would be drawn to the nucleus by an irresistible force; nucleus and electrons would be a compact mass, and all space between the nucleus and the extranuclear electrons would practically be eliminated. This, however, is contrary to all experimental data. What, then, offsets this irresistible attraction?

Physicists have taken their cue from the planetary system of the sun and its satellites. That the earth, for example, does not succumb to the centripetal gravitational attraction of the sun and become one mass with the latter, is due to the centrifugal force of its orbital movement around the sun; the one force balances the other. So, too, physicists argue, an orbital revolution of the extranuclear electrons is required to equalize the electromagnetic attraction of the nucleus. Electrons, therefore, *revolve in orbits* around the central nucleus.

A serious objection was raised against this view of revolving electrons. In describing such orbits, these high-speed electrons should lose energy through radiation, slow down in their velocity, and gradually spiral into the nucleus. *Niels Bohr*, however, showed that this result need not happen, if it be borne in mind that radiation takes place only in the event that definite *quanta of energy* be given up or absorbed by the revolving electron. If we assume various energy levels and energy states in the atom, it would be possible for an electron to revolve in certain orbits and at

certain levels without any radiation. If the electron is forced from its prescribed orbit, photons would be either absorbed or emitted in specified quanta of energy. The hydrogen electron, for example, has a normal orbit. But there are a number of other possible orbits in which it can move. When forced to leave its normal orbit and move in one of these, energy will be expended which manifests itself in the *spectral lines* of hydrogen. This would account for the numerous lines found in the spectrum of hydrogen and other elements. The frequency of the light emitted by the atom would then be the result of a change in the *energy state*; it equals the energy loss divided by Planck's constant h . Experiments and calculations bear out the Bohr theory that the electron emits either a whole quantum of monochromatic radiation or no energy at all. Planck's constant has the dimensions of energy x time, or momentum x distance, and this is termed an 'action.' So long, then, as an electron had an amount of action equal to h or an integral multiple of A , its orbit would be non-radiating or 'stationary'; this would be the natural and preferred orbit for this electron. Whenever, then, an electron makes a 'transitions from one level to another within the shells of the atom, a quantum of energy is absorbed or radiated, and a spectral line is the result. This is a beautiful explanation of the lines of the spectrum known as the *Lyman* series, *Balmer* series, *Paschen* series, and Brackett series.

Various considerations in connection with spectroscopy have inclined physicists to the view that even the revolution of the electrons around the nucleus will not suffice to

account for all the phenomena. The electrons must have a type of angular momentum different from that of its revolution in an orbit. And so the individual electron is conceived as having a *spin on its own axis*, similar to the revolution of the earth on its own axis. Now the atom bears a close resemblance to a solar system, and we have an 'astronomical atom.'

THE ATOM AND WAVE MECHANICS

Although the Bohr theory of the atom, with its electrons rotating around the nucleus as particles or 'charged mass points,' proved very successful in explaining many phenomena of atomic physics, it failed in some important points and seemed to lead to contradictory results. In the opinion of many physicists, it leaned too heavily on the Newtonian mechanics which apply to large bodies; it did not take into full account the behavior of electrons as 'waves.' The attempt has been made in more recent years to explain the atom on the basis of 'wave mechanics' rather than on the basis of 'body mechanics.' The idea of 'wave particles' or 'matter waves' was broached by *Louis de Braglie* in 1925; it was developed into a full fledged theory in subsequent years, notably by *Dirac*, *Schrödinger*, and *Born*. It is difficult to give an adequate presentation of this theory in a brief statement, but the main trend of thought is as follows.

Just as light appears both as particles and as waves, so also do the electrons. Mechanics proved incapable of informing us precisely where an electron could be found in

its orbit; it seemed, rather, to be spread over the entire shell or orbit. Perhaps, then, we should relinquish the idea of the electron as a minute particle or mass point and treat it as *electrical matter moving as a system of waves*. Electrons would not only have energy and impulse, but also the frequency and wave length associated with waves. The electron would indeed be a wave occupying the whole orbit, with crests and troughs following in definite sequence. Under ordinary conditions electrons can be regarded as particles, because their wave nature cannot be detected, due to their extremely short wave length; when, however, their wave length approaches that of X rays or light, their wave nature should be able to be detected, as it is observed in the very fine grating of a crystal lattice, where photons and electrons both show the characteristics of waves (diffraction and interference patterns). This applies not only to electrons. but also to molecules, because *Stern* and *Estermann* in 1930 obtained diffractions of hydrogen and helium. According to de Broglie, electrons as waves could be represented in the following manner:

Calculations show that each frequency has a definite value so far as energy is concerned; *n* other words, the quantization of the frequency involves automatically quantization of the energy. Hence, only energy levels of a definite value can exist in each atom, and these are characterized by whole numbers. Schrödinger's theory of wave mechanics has enabled physicists to explain many

phenomena of a spectroscopic nature much more satisfactorily than did Bohr's model.

It would be erroneous, however, to think that the theory of wave mechanics has solved all difficulties. On the contrary, new difficulties arise from the theory. We do not know, nor are we told, what it is that vibrates and acts like a wave. In the opinion of Schrödinger, we have a condensation and rarefaction of electric charge distributed over the length of the wave structure. When the vibration is strong at any point, there the density of the electric charge is strong; it is strongest at the loops and weakest at the nodes. The charge, therefore, is not concentrated in a mass point, the electron, but distributed in various degrees of density over the whole wave. The electron as a 'particle' has dissolved into a 'charge cloud'; instead of a solid corpuscle we have a denser or rarer fog.

There are serious *objections* to this view. If the charge of the electron 'cloud' is so distributed, the separate parts of the negative cloud of the wave electron must exert forces upon one another, and no account is given of such influences. Then, too, the theory apparently cannot explain the obviously corpuscular character of the electron streams as observed in the cathode rays; they do not behave like waves, but as projectiles and solid particles. Schrödinger contends that the cathode rays are not particles, but 'wave packets.' However, it seems impossible for such 'wave packets' to remain together and not be dissipated, so that the stability of bodies is rendered inexplicable. Apparently, therefore, the *dualism of the particlewave* still remains,

because wave mechanics cannot give an adequate explanation of the energy and impulse found in matter.

Max Born, in 1926, offered a solution for this perplexing problem of the particle and wave nature of matter. Consider light. In the wave theory, the higher the wave crest, the brighter the light. In the photon theory, the larger the number of arriving photons, the brighter the light. If we unite the wave and photon theories, photons and waves both exist, and the height of the wave crest would be the measure of the number of photons present; the photons would be present in the crests. Interference and cancellations of waves would occur without destroying the photons themselves. The waves control the motion of the photons and determine the average number of photons arriving at any particular point. The same hypothesis is made to apply to matter, to electrons and protons. We can never determine the exact position of particles; all we can know is their 'probability distribution' in space. *Heisenberg* had already enunciated his *principle of indetermination or uncertainty*, in virtue of which it would always be impossible to determine at any time the exact position and velocity of an electron: if the position is known, its velocity cannot be determined; if the velocity is known, its position cannot be determined.

Whatever we may think of these attempts to harmonize the particle and wave characteristics of matter, specifically of the electron and photon, it must be recognized that the problem has not been definitely solved. Neither theory dispels the darkness surrounding the atom. The difficulties are increasing, not diminishing.

ATOMIC STRUCTURE AND VALENCE

The vast majority of atoms have no isolated existence. They combine with atoms of other elements to form compounds. But atoms do not form compounds at random. They unite in definite proportions, and more readily with those of some elements than with those of others. *Valency* plays an important part in chemical combinations.

Valency, or valence, is defined as the combining capacity of atoms in forming chemical compounds. Valence is measured in terms of hydrogen atoms. The hydrogen atom is the simplest of all and is a natural unit, since it consists of but a single proton and electron. It is a very active element and forms compounds with a large number of elements. The combining capacity, or valence, of elements is, therefore, measured by the number of hydrogen atoms with which they will combine to form a compound or which they will displace from a hydrogen compound. Any element which displaces, or combines with, 1 hydrogen atom is a *monovalent or univalent* element; one which displaces, or combines with, 2 hydrogen atoms, is *bivalent*; 3 hydrogen atoms, *trivalent*; 4, *quadrivalent*; and so on. For example, a chlorine atom will unite with 1 hydrogen atom (HCl); it is monovalent, i.e., chlorine has a valence of 1. Oxygen unites with 2 atoms of hydrogen (H₂O); it is *bivalent*, i.e., oxygen has a valence of 2. Nitrogen has a valence of 3, because an atom of nitrogen will unite with 3 atoms of hydrogen (NH₃). Again, magnesium will displace 2 hydrogen atoms from water and form MgO; magnesium thus has a valence of 2.

Carbon and sulphur will displace 4 hydrogen atoms, forming CO_2 and SO_2 both, therefore, have a valence of 4.

Valence is readily *explained* by the nuclear atom with its *orbital electrons*. The inert gases form a completely balanced structural system and are nonvalent. The other elements possess electrons in their outer shells in an unbalanced condition; they can give or take electrons and form compounds. Lithium, for instance, has one electron outside its 'helium shell.' On the other hand, fluorine has seven electrons outside its 'helium shell,' lacking one electron to complete the balanced and stable octet characteristic of neon, the element next to fluorine. Lithium, therefore, should be able to give its extra electron to fluorine; thereby lithium would resemble the stable helium, and fluorine would resemble the stable neon. United, they should form a stable compound; and this is actually the case. The chemical reaction between them is represented in the following diagram:

While both fluorine and lithium are monovalent, the difference between the two elements is obvious. Fluorine receives an extra electron to fill in its octet and thereby obtains a unit charge of negative electricity in excess; the fluorine atom becomes a *negative ion* (F^-), and the fluorine element is typically *electronegative*. Lithium, however, loses

an electron and thereby has a unit charge of positive electricity in excess; the lithium atom becomes a *positive ion* (Li^+), and the lithium element is typically *electropositive*. The basic or metallic elements are all electropositive in character, while the acidic or nonmetallic elements are all electronegative; and the reason is clear.

Oxygen has a valence of 2, because it can combine with two hydrogen atoms to form water (H_2O). This action can also be shown diagrammatically:

Oxygen lacks two electrons in its outer shell to complete its octet. The hydrogen atom has only a single electron to give away; it is monovalent. The oxygen atom, therefore, requires two hydrogen atoms to fill its outer shell; it is bivalent. One oxygen atom and two hydrogen atoms form a stable compound (H_2O).

Beryllium, however, is a bivalent element; one atom of beryllium will unite with one atom of oxygen to form beryllium oxide. The structure of the beryllium atom

explains this chemical fact; it has two electrons outside its 'helium shell' which it can release to the oxygen atom.

Valence, therefore, is determined by the number of *transferable electrons*, and the number of transferable electrons is determined by the number of electrons in the *outer shell* of the atom. Such electrons are called 'valence electrons,' and the transfer of such valence electrons is termed 'electrovalence.' Since the phenomenon of valence, both electropositive and electronegative, is typical of all elements according to their 'group properties,' it would seem in general to receive a neat explanation in the *structural arrangement* of the orbital electrons in the atom. This would also explain a great deal (though by no means everything) about *chemical affinity*, the natural tendency which elements possess of forming compounds with definite other elements.

THE CUBICAL ATOM

Chemists, who naturally seek a model of the atom which will explain chemical combinations and reactions, do not find it easy to harmonize the 'mad dance' of electrons in their orbits, as postulated by physicists, with the phenomena peculiar to their own field of research. Since the electrons are conceived as whirling in their respective shells around the nucleus at terrific speeds, it is difficult to understand how the *transfer of electrons* can take place from one atom to another and how a real compound can be formed.

In opposition to the 'astronomical' or 'planetary' model of the atom, *Gilbert N. Lewis* advanced the theory of the

'cubical' atom as more in agreement with chemical facts. According to this view, the electrons are arranged in concentric cubes around the nucleus. Since the cube has eight corners, the octet formation, with an electron at each corner, is the most symmetrical and balanced system possible for an atom. The completed cube, with its octet of electrons, finds its realization in the inert gases (with the exception of helium which, due to the small number of its electrons, has only two outer electrons). Atoms with incomplete outer cubes may either give away electrons to complete the octets of other cubes or accept electrons to complete their own octets; this explains ionization and positive and negative valence. When one cube of eight electrons is completed, the following series of elements forms another cubical shell of electrons, until at the end of the series the next inert gas forms a cube with eight electrons in its outermost shell.

Lewis considers the *pairing of electrons* to be even more important than the fact that atoms demand the *octet formation* in their outer shells. He points out that of hundreds of thousands of known substances very few have odd numbers of electrons in their valence shells; valence electrons are, therefore, almost universally found in a molecule to be multiples of two. Molecules with odd-numbered valence electrons possess singular properties; they are highly paramagnetic, very reactive, and tend to form molecules with electrons of even numbers. Such pairing neutralizes the magnetic field and eliminates the magnetic moment. Due to this pairing or coupling of electrons, Lewis later inclined to the view that the stable

octet is not so much a cube of electrons, but rather a *tetrahedron* possessing a pair of electrons at each of its corners.

The *chemical bond* between atoms in a molecule is nothing more nor less than a pair of electrons which two atoms hold jointly. Valence electrons may be *relinquished* by one atom and given to another, so that both atoms have a complete octet formation; or, valence electrons may be shared in common by the shells of two atoms. This would explain the 'polar' and nonpolar' types of chemical combinations. When two pairs of electrons are *shared*, there is a double chemical bond; when three pairs, a triple bond. This 'sharing' of electron pairs is styled *covalence* and is typical of nonpolar compounds.

Frederick Soddy, the eminent chemist, is convinced that the Lewis-Langmuir 'cubical' atom is a far more appropriate model for explaining chemical phenomena than the Bohr and Schrödinger 'astronomical' atoms in their highly commotional states. The former model meets the requirements of the chemist to a remarkable degree; the latter satisfies the physicist better for the solution of his particular problems. Both models are speculative and theoretical; perhaps neither model represents the actual condition of the physical atom as it exists structurally in nature. The atom is, and will probably always remain, a most mysterious entity.

CRYSTALLIZATION

Research into the properties and structure of crystals throws considerable light on the nature and arrangement of atoms and molecules in bodies. Although it is customary to divide bodies into 'crystalline' and 'amorphous,' it is now generally recognized that all elements and compounds crystallize under certain given conditions.

Crystals are inorganic structures arranged in well-defined *geometric forms*, with definite *planes*, *axes*, and *angles*, irrespective of their size. Every substance assumes a *specific crystal form* characteristic of this particular substance, and the angles between its faces are peculiar to this substance. The cube has perfect symmetry in all directions; but all crystal forms, of whatever kind, possess symmetry of structure. Furthermore, every crystalline substance possesses its own *characteristic physical properties*, such as elasticity, density, electric constants, and optical refraction. Distortion of form occurs in crystals, but this is due to impurities or to interference in their development on the part of adjacent bodies. The quantity of material on hand determines the size of crystals, but not their specific form or shape.

Many crystal substances are *dimorphous* and even *polymorphous*; that is to say, they are capable of assuming 'two forms' or 'many forms,' depending in most cases upon the fact whether they crystallize above or below a certain critical temperature. Examples of dimorphous substances are calcium carbonate (CaCO_3), and mercuric iodide (HgI_2). Examples of polymorphous substances are dioxide of titanium (TiO_2) which appears in three forms (anatase, rutile, and brookite), and ammonium nitrate which assumes

four different crystal forms as it passes from its melting point 168°C to 125°, to 83°, and to 32°. Even simple elements may assume different unrelated crystal forms, as in the case of sulphur and carbon; carbon, for example, appears as graphite and as diamond.

The regularity with which chemical substances assume crystalline form is, of course, not a fortuitous event; it is the result of a law operating among the molecules and atoms. It has long been held that the characteristic arrangement of molecules and atoms in the crystal is due to the forces present in the molecules and atoms themselves, and not to some outside force imposing a shape upon them. The *spontaneity of formation* is proof of this.

That the *atomic constitution* of the elements plays the predominant part in the form and type of crystals, is now admitted by all crystallographers. This is to be expected, since the forces emanating from, and operating in, the atoms are the very forces which control the combination of atoms into molecules and of atoms and molecules into crystals. For instance, potassium, rubidium, and caesium are alkali metals of Group I; they are very similar in chemical and physical properties. There is also a decided similarity in the crystal forms of potassium sulphate, rubidium sulphate, and caesium sulphate. The differences between them are found to be in proportion to their differences in atomic weight and number, as can be seen by replacing one element by others. The same applies to the selenates and atomic groups in general.

A crystal thus becomes an index to the inner constitution of the atoms which are the ultimate building stones of the

crystal and confirms the findings of physicists and chemists regarding the placement of elements in the periodic table.

Modern *X-ray technique* has greatly advanced our knowledge of the arrangement of molecules and atoms within the framework of the crystal. X rays reveal the inner structure of crystals. The 'Laue patterns' made by X rays on a photographic plate, after passing through a crystal, show definitely that crystals consist of a 'unit of pattern' multiplied over and over throughout the structure of the crystal, and each unit lies up against the adjacent unit with utmost precision, so that the relative position and distance of these units is the same everywhere in the crystal. Crystals are not absolute solids; the atoms, or molecules, are arranged in a *space lattice*, occupying the corners and forming *cells* of definite configuration ('unit cell'). Each cell contains the same number of atoms or molecules of the crystalline substance. Thus, each unit cell of rock salt contains one molecule, namely one sodium and one chlorine atom; the unit cell of diamond, two atoms of carbon; the unit cell of quartz, three molecules of silicon dioxide; and so forth.

By measuring the angle of reflection made by the incident ray and the set of planes in a crystal, scientists are capable of calculating with great accuracy the dimensions, volume, and form of the unit cell, the type of lattice, the mass with the number of molecules and atoms in the cells, and the relative disposition of these molecules and atoms. At any rate, such is their claim, and crystallographers produce much evidence to substantiate their findings. All in all, the intensive research work made on crystals and

crystallization confirms the findings of the physicists and chemists in other fields.

Much of what has been stated in this chapter on the structure of matter is scientific theory and not observational fact. It cannot be otherwise. Atoms and molecules have diameters which are shorter than the shortest wave length of visible light; hence, they can never be observed by the human eye. This does not mean that they are fictions of scientists. Our knowledge of these corporeal entities is acquired through indirect methods. This being so, scientific theory must naturally play a large part in the proper *interpretation* of the facts which science has succeeded in uncovering. And where there is theory, there may, of course, be a legitimate divergence of opinions as to the correctness of this interpretation. While this is true, it must be admitted by the impartial student that the general scientific theory of the structure of matter, and also of the structure of the atom, is based on data obtained from diverse and independent experimental sources; it should, therefore, be accepted, at least in its *fundamental features*, as highly probable. On the other hand, it must also be admitted that our factual knowledge of the atom and its structure is still very limited.

SUMMARY OF CHAPTER V

The atom is the fundamental unit of inorganic bodies.

1. *The Structural Atom.* Atoms are complex entities and possess structure. This is concluded from the periodic recurrence of group properties between one Zero element and the next. The difference existing among the elements is not due to their mass or number of particles, but to difference in their *positive charges*. Ionization and radioactivity show that some electrons must be closely united to the positively charged masses, while others are more loosely united. Hence, not all electrons have the same position and function in the atom.

From the small number of collisions between alpha projectiles and atoms, and from the angle of scattering of alpha particles, Rutherford deduced the *nuclear atom*. This atom consists of a central mass of net positive charge with a field of negative electrons stationed at relatively great distances from it. This theory of the 'nuclear atom' offers a good explanation of atomic weight and atomic number, of ionization and transmutation, of isotopes and isobars.

2. *Electronic Shells.* The arrangement and position of the extranuclear electrons in shells explains the existence of electropositive and electronegative elements, of the inactive Zero elements (helium, neon, etc.), and of the periodic recurrence of group properties in the Periodic Table. The completion of an octet of electrons in the outermost shell gives rise to a new Zero element.

Within each shell, physicists claim, there must be a definite number of energy levels.

3. *Revolving and Spinning Electrons.* In order to account for the fact that electrons are not drawn completely to the positively charged nucleus, due to their electromagnetic attraction, Bohr assumes that the extranuclear electrons must revolve in *orbits*. The transition of an electron from one orbit to another would demand the emission or absorption of a quantum of energy; this accounts for spectral lines. Various considerations in connection with spectroscopy have also inclined physicists to accept an individual *spin* in the electron. More recent theories attempt to harmonize this 'astronomical atom' with *wave mechanics*.

4. *Atomic Structure and Valence.* Valency, or valence, is the combining capacity of atoms in forming compounds. It is measured in terms of hydrogen atoms; the number of hydrogen atoms with which other atoms will combine to form a compound or which they will displace from a hydrogen compound, determines their valence. The orbital electrons are the valence electrons. These electrons can be transferred from one atom to another, accounting for electropositive and electronegative valence, for group properties, for affinity between elements, and for the formation of chemical compounds.

5. *The Cubical Atom.* Chemists are not quite satisfied with this commotional dynamic atom. Lewis advanced the theory of the 'cubical atom' as more in agreement with chemical facts. According to this view, the electrons are arranged in concentric cubes around the nucleus; in the

completed cube the octet of electrons would be such that one electron is situated at each corner of the cube. Due to the 'pairing' or 'coupling' of electrons, Lewis later advocated a tetrahedral form for the atom, instead of the cubical form.

6. *Crystallization.* Crystals are inorganic structures arranged in well-defined geometric forms, with definite planes, axes, and angles, irrespective of their size. Every substance assumes a *specific* crystal form, possessing characteristic physical properties, determined by the internal forces of the atoms and molecules. Atoms and molecules are arranged in a *space lattice*, with unit *cells* of equal dimensions.

PART II

**THE GENERAL PROPERTIES OF
BODIES**

Chapter 6

QUANTITY AND EXTENSION

RECENT INVESTIGATIONS INTO THE PHYSICAL constitution of inorganic bodies have revealed many interesting and important facts. There are about 92 distinct elements or types of atomic bodies. Atoms are themselves composed of subatomic particles, namely, electrons, positrons, protons, and neutrons. Electricity is a concomitant feature of all matter. The mystery of electricity, however, has not been cleared up, because we do not know wherein consists the intrinsic difference between positive and negative electricity. While there is still very much to investigate, we have learned that a definite minimal quantity of electric charge is bound to a definite minimal quantity of matter. These quantities, though exceedingly small, possess a distinctly measurable magnitude.

This brings us to the consideration of a property of all bodies which is fundamental and universal in character — *quantity* and *extension*. Closely allied to the concepts of quantity and extension are the concepts of *place* and *space*, *motion* and *time*. These will now be treated at some length.

EXPERIENCE OF QUANTITY AND EXTENSION

Bodies occupy space. That is to say, they have length, width, and depth; they are spread out in three dimensions, and these dimensions can be measured in units or fractions of centimeters, inches, or of whatever standards of measurement we choose to employ.

Our experience of dimensions is based on the commonplace and scientific *observation of our senses*, particularly those of sight and touch. Sight reveals at least two dimensions, length and depth. Everything we see is spread out, with parts which are right and left, up and down; all have surfaces which are horizontal and vertical. The sense of touch, however, reveals most clearly the triple dimensions of a body. Man is intuitively aware through touch of three dimensions in his own body. Movement of the hands over one's own body manifests surfaces which have length, width, and depth. Our own body is recognized as something which belongs to our being. That, however, is not all. Contact manifests the presence of 'other bodies' which do not belong to our being but have a being distinct from our own. They are perceived to have an existence and an entity as real and as actual as our own body, even though they form no part of it. The desk at which I sit and write, the house in which I live, the street over which I walk, the buildings which I visit — all are observed to possess the common three dimensions. They have *extension, quantity*.

We also observe quantity in a different way. There is quantity in the *degrees* in which physical realities appear, expressing a 'more-or-less' of something. Temperatures are

warmer or colder, weights are heavier or lighter, electric currents are stronger or weaker, hurts are more painful or less painful, and so forth. Observations of such a kind involve the concept of quantity.

Then, too, we observe quantity in the *numbers* of concrete objects. We see twenty people in a room, ten houses in a row, five trees in a field, two automobiles passing down the street, a single dog asleep on a doorstep, etc. Numbers always imply quantity.

Scientific observation is not of an order different from that of everyday life; it rests ultimately on the senses, and these are alike for all men. Scientific observation, however, has enlarged the field of research through the use of such instruments as the telescope, the microscope, the spectroscope, the thermometer, etc., thereby obtaining a more refined and critical knowledge of many things which lie beyond the ken of the unaided senses. Much of this scientific knowledge is the result of more accurate measurement. To measure a thing is, for many scientists, almost the same as to know a thing. It thus happens that the quantitative side of material things is often the sole object of research in scientific investigation. At any rate, scientists readily acknowledge that all bodies are affected by quantity as a fundamental property of physical nature; quantity is taken by them more or less for granted.

The philosopher must, therefore, examine 'quantity' and 'extension,' in order to acquire a deeper knowledge of these realities.

CONCEPT OF QUANTITY AND EXTENSION

Strictly speaking, *quantity cannot be defined*. In order to give a true, philosophical definition of it, one would have to define it by means of *genus* and *specific difference*. The genus must express that essential part of the subject which it has in common with other species in the same class, and the specific difference must express that essential part of the subject which distinguishes it from every other species under the same genus; together, the genus and specific difference express the complete essence of the subject defined.¹ The only concepts which could possibly be used as a genus in the definition of quantity would be the concepts 'accident' or 'being,' and such a genus must be predicated of its members in an identical sense, i.e., univocally. That, however, is not the case. The concepts 'accident' and 'being' are not a true genus; their meanings are predicated of the class concepts under them only in an analogical, not in a strictly univocal, sense.² Hence, it is impossible to give more than a descriptive definition of it.

Aristotle, in his usual compact and felicitous manner, defines a quantum (something that is 'quantified,' or possesses 'quantity') as *that which can be divided into its inherent components, each of which* (after the division) *is a single and complete whole*.³ It should be noted that Aristotle's definition is frankly descriptive. It defines a *quantum* or concrete reality which possesses quantity, rather than 'quantity' itself; and it defines it by means of 'divisibility,' which is a resultant of quantity. He could, of course, have defined 'quantity as the property of a thing in

virtue of which it can be divided into its inherent components, each of which is a single and complete whole'; but this abstract form does not change the definition itself.

Let us analyze Aristotle's definition. He says that a *quantum* or quantified reality is 'that which can be divided.' Since it can be divided, it is a whole which is *divisible*; being merely divisible, before the division it is as yet *undivided*: it is a whole which is as yet undivided, but capable of being divided, into its components. These components cannot be present in the whole as *actual* parts, otherwise the division has already taken place, and the thing would no longer be a 'whole capable of division.' In the quantified whole itself the components can only be *potential* parts which become actual only after division. In other words, a thing is said to have quantity, when it is actually one, a unit, an undivided whole; it is, however, potentially multiple, so that after the division the original whole becomes two or more units, each of which is now an undivided whole for itself.

An example will clarify this. A line six inches in length does not consist of six distinct lines in a row, each of which is one inch long; on the contrary, it is a single line, a unit, an undivided line. If we cut this line equally in two, we have two lines of three-inch lengths; if we cut it into three equal parts, we have three lines of two-inch lengths; if we cut it into six equal parts, we have six lines of one-inch lengths; if we cut it into twelve equal parts, we have twelve lines of half-inch lengths. Before the division the line has neither two, nor three, nor six, nor twelve 'actual' parts, because it is simply *one line*; it is, therefore, an undivided whole. Since, however, it is divisible into any of these lengths,

these various lengths are ‘potential’ parts present in the line as a whole; the line is thus seen to be *potentially multiple*, though actually one. After the division, the original single line results into two or more lines, each of which is shorter in length than the original; but each one is again a line for itself, a complete and undivided whole line. The following illustration shows this plainly.

Here we see that *A* is one, a unit, a complete whole, an undivided but divisible line. On the other hand, *B*, after the division of *A* has been made, is actually three lines, each of which is again a single and complete whole, an undivided but divisible line, of the same kind and nature as the original line.

We thus see the truth of Aristotle’s definition, that a quantum is that which is divisible into its inherent components, each of which is a single and complete whole. Two things are required for a thing that is said to be affected by quantity: first, the parts or components into which it can be divided must be present in it before the division, so far as their *reality* is concerned, though they are not there formally as parts; second, these parts or components must be such that, once the division is actually made, they themselves now exist as single and complete *wholes* of the same kind as the original whole from which they derive their origin.

KINDS OF QUANTITY AND EXTENSION

Quantity can be classified in various ways, depending on the difference of viewpoint.

Continuous and Discontinuous Quantity. Quantity is said to be 'continuous,' when it is uninterrupted in its being, so that the components within it are united by *common limits* or *boundaries*. The components are not divided from one another, each having limits or boundaries of its own; they have no limits or boundaries except those of the whole to which they belong, and they are thus united within and by the common limits or boundaries of the whole. For example, the parts of a line have no limits within the line, but are bounded only by the extreme limits of the whole line itself; everything contained within a sphere has no limits inside the sphere, but is bounded solely by the outside limits of the sphere as a whole. If the components of a line or a sphere had boundaries of their own, there would not be a line and a sphere, but a number of lines and segments of a sphere, each possessing a distinct entity. The components of a continuous quantity, therefore, are not an actual multitude of realities in juxtaposition, but one reality; they form an actually undivided, though divisible, whole. *Aristotle* defines a continuous body as one 'whose extremes (limits) are one.

A *discontinuous* or *discrete* quantity is a quantity which consists of components, each of which is an entity for itself, with its own complete limits or boundaries; together, they form some sort of unit or whole in a wider sense. There are two kinds of discontinuous quantities: contiguous and separate. A *contiguous* quantity is one whose components

are in contact at their boundaries. Examples are: billiard balls touching each other; two boards nailed together; the wheels of an automobile and the axle; the human body and the clothes enveloping it; a house and the air surrounding it; the pages of a closed book. A *separate* quantity is one whose components are at a distance from one another and are united by some other intermediate reality, so that their boundaries are not in immediate contact. Examples: a complex of buildings belonging to the same institution; the bricks of a wall united by mortar; a number of cars forming a train; a group of soldiers lined up as a squad or company; a multitude of separate flowers arranged in a design. In these and similar instances there is a definite unit or whole, but each component is a distinct quantity for itself, having its own individual limits or boundaries. The result is not a continuous quantity, but simply a *group* of wholes united into a looser quantitative whole. *Numbers* are discrete quantities.

Continuous and contiguous quantities may be *perfect* or *imperfect*. They are perfect, when they are uninterrupted throughout their entire reality; imperfect, when they are partially interrupted. A solid block of material, for example, is a perfect continuous quantity, and so, too, is an unbroken surface; but a porous block and a surface with perforations through it are imperfect continuous quantities. Two surfaces, touching each other over their entire area, are perfect contiguous quantities, but two surfaces, touching each other over only a part of their adjacent area, are imperfect contiguous quantities. Separate quantities, since they do not touch each other, are always perfect separate

quantities; if they touched at any point, they would be contiguous, not separate, quantities.

There are, consequently, five possibilities concerning the quantities just mentioned, and they are illustrated in the sub-joined diagrams:

A, represents a perfect continuous quantity; *B*, an imperfect continuous quantity; *C*, a perfect contiguous quantity; *D*, an imperfect contiguous quantity; *E*, a (perfect) separate quantity.

Dimensive, Intensive, and Successive Quantity. *Dimensive* quantity is a quantity of extension, of magnitude. Lines, surfaces, and solids belong to this class, because they have dimensions in one, two, and three directions. Any object that occupies space has *dimensive* quantity. Continuous and discontinuous quantities, if they refer to areas, are of this type. *Intensive* quantity is a quantity of degrees, inasmuch as there is an increase or decrease of intensity present. Light, action, heat, electricity, magnetism, and most qualities and energies, admit of an increase or decrease in their intensity. *Successive* quantity is a quantity comprised of components which follow one another in sequence. Motion and time are of this character; the elements of motion and time do not coexist simultaneously, but successively, one element immediately following the other. In order to cover these various types of quantity, we

may describe quantity in general as that *property of a thing by virtue of which measure or number or division is applicable to it*.

What interests the philosopher particularly, is the *nature of a continuum*, i.e., of a reality possessing continuous quantity, continuous extension. Quantities which are discontinuous, whether contiguous or separate, are ultimately composed of *continua* either in contact or at a distance. Hence, if we understand the nature and properties of continuous extension, we also understand the nature and properties of contiguous and separate quantities. Motion and time will receive special treatment in a subsequent chapter.

DIVISIBILITY OF A CONTINUUM

The first problem before us relates to the *divisibility of a continuum*. A continuous quantity, as we have seen, is conceived as an unbroken and uninterrupted extensive whole which is undivided but divisible; it is actually one, but it is also potentially multiple, inasmuch as it can be divided into multiple units. Divisibility presupposes components in the single and complete whole. A thing is said to have *indivisibility* when it does not contain components into which it can be divided. Indivisibility may be either physical or metaphysical. It is *physical*, when there is a natural limit to the divisibility of a (physical) body, due to the absence of means or instrumentalities capable of effecting further division. Such, for example is the present impossibility for the physicist of dividing an electron or proton into smaller

portions. It is *metaphysical* or *mathematical*, when the thing in question does not contain entitatively diverse parts into which it could be divided; since there are no parts into which the thing could be divided, divisibility would involve a contradiction in terms. From the standpoint of extensive quantity, a mathematical *point* is indivisible, because it has no parts and is unextended; it is rather the limit and negation of extension. While no one questions the fact that a material body in concrete nature consists ultimately of parts which are 'physically indivisible' (electrons, protons, etc.) the problem is whether the ultimate extended bodies are also 'metaphysically indivisible.' In other words, taking extension *absolutely and simply* as a continuous quantity, do we ultimately arrive at parts which are metaphysically and mathematically indivisible, or can division go on interminably ad *infinitum*?

Naturally, if a *continuum* is divisible, it must somehow consist of parts; where there is divisibility, there must be some sort of composition. *Zeno*, a philosopher of Flea in ancient Greece (born about 490 B.C.) maintained that every *continuum* is ultimately composed of parts which are mathematically indivisible, i.e., points devoid of all extension; hence, a *continuum* is not infinitely divisible. *Aristotle* (384—322 B.C.) defended the view that continuous extension as such is infinitely divisible, so that it is impossible to arrive at the limit of mathematical division. Some more recent philosophers, as *Leibnitz* (1646—1716), *Boscovich* (1711—1787), *Fechner* (1801—1887), and others, claimed that extended realities consisted ultimately of unextended and indivisible parts, which occupy a certain

field of space through their force and can thus be said to be virtually, though not actually, extended; in this way they attempted to account for the fact of extended bodies and to obviate the necessity of an infinite divisibility.

We follow Aristotle and contend that a continuum, considered purely and simply as an extended quantity, is *infinitely divisible*, in a mathematical sense, *into proportional parts*, i.e., into parts which are halves, thirds, fourths, etc., of the original quantity. It should be obvious that it is impossible to divide extension infinitely into centimeters, meters, kilometers, or similar divisions based on some standard unit of measurement.

PROOF OF INFINITE DIVISIBILITY

If continuous solids, surfaces, and lines were not infinitely divisible, it could only be because they are composed ultimately of indivisible components. Were these ultimate components extended in any way, they would again consist of components into which they could be divided; in that case they would not be indivisible components. The only reason why the ultimate components of a continuous quantity can be said to be indivisible is, because these ultimate components themselves have no parts and are unextended; but such entities are, by definition, *mathematical points*. Now, mathematical points have no extension. Since the individual points have no extension, any sum of points, even a million or a billion or any other amount, cannot have extension. Consequently, no sum of mathematical points can possibly form a line, or a surface,

or a solid. If, then, a continuous quantity (line, surface, solid) were conceived to consist ultimately of indivisible, unextended components (points), no quantity with a continuous, divisible extension could ever result. But the supposition is, that there is such a reality as a continuum. Consequently, a continuum cannot consist ultimately of indivisible, unextended points. Hence, since the division of a continuous quantity can never reach indivisible, unextended points without parts, the components into which a continuous quantity can be divided will always be extended components. But extended components, not consisting of points but of components with parts, can again be divided into smaller components or parts, *without ever arriving at indivisible points*. The divisibility of a continuous quantity, therefore, can go on without limit. Divisibility without limit, however, is infinite divisibility. Hence, a continuum possesses infinite divisibility in a metaphysical or mathematical sense.

This can also be proved *mathematically*. Draw two lines, AB , and CD , parallel to each other. Extend a line EF from AB to CD , forming right angles to the parallel lines. Draw a line GH , starting from G to the left of EF on the line CD , and arriving at H to the right of EF on the line AB . The line EF will now be intersected. Draw other lines from G to H^1 , H^2 , H^3 , etc. Each line will intersect EF . Since the line AB can be extended infinitely, and since a line from G can be drawn mathematically through EF to AB along the entire length of AB , there is no limit to the divisibility of the line EF . This divisibility would cease only when the line AB coincides and coalesces with CD . But the lines AB and CD are parallel and

can never coincide and coalesce. Hence, the divisibility of the line EF can never reach a limit; it is limitless. But a limitless divisibility is infinite divisibility. Consequently, a continuous line (and the same applies to a continuous surface and solid) has *infinite divisibility*.

This shows that the division of the line EF , as indicated, can never arrive at an unextended portion or mathematical point. The portions, after each successive division, become smaller and smaller, but each remaining portion is *still extended* and therefore still divisible.

These and similar arguments definitely dispose of the contention that continuous quantity consists ultimately of indivisible and unextended points. However, to refute *Zeno* and his adherents more directly, consider the following argument. If his contention were correct, that every continuous quantity is composed of indivisible, unextended points, the conclusion is inevitable that *difference in speed is impossible*: A racing automobile could travel no faster than a snail, and a snail could travel no slower than a racing automobile. In traveling in a straight line, the automobile cannot cover more than one point in one moment of time, because the indivisible point is the smallest portion of space and the indivisible moment is the smallest portion of time. But neither can the snail cover *less* than an indivisible point

of space in an indivisible moment of time. Consequently, both the racing automobile and the snail cover neither more nor less than one point of space in one moment of time; hence, their speed must be identical. That, however, is patently untrue. Therefore, the original supposition is wrong, that a continuous quantity is composed of indivisible, unextended points. As a matter of fact, if this were true, *all motion would be impossible*. A point, being unextended, occupies no area; and a million points occupy no area. Hence, in traveling over points, the supposedly moving object covers no area by passing from point to point. Motion, however, necessarily implies that the moving object covers a certain area in a definite direction. Motion is an undeniable fact. Consequently, areas (i.e., continuous quantities consisting of lines, surfaces, and solids) cannot be composed ultimately of unextended points.

The advocates of *virtual extension* are no more successful than Zeno in the solution of the difficulty which they find in the aristotelian *continuum*. According to their view, the infinite divisibility of extended quantity, as defended by Aristotle, involves the idea of an actually infinite number of parts in every extended body; an actually infinite number, however, is contradictory and therefore impossible. On the other hand, they admit that absolutely simple and unextended points can never account for the extension which is, to all appearances, present in bodies. To obviate this double difficulty, they postulate the existence of 'virtual extension'; the ultimate components of bodies are indivisible and unextended points, but their force extends into the intervening and surrounding space, and it is thus

that extension arises. This theory, however, will not solve their difficulty. Three items enter into their problems: unextended *points*, *space*, and *force*. Now, this intervening space is either continuous in an aristotelian sense, or it is not. If it is continuous, they contradict themselves, because they accept the aristotelian *continuum* which, as they contend, involves an actually infinite number of parts. But if they are willing to accept an infinite number of parts in space, there is no reason why they should not be willing to accept the same situation for the bodies themselves, and they are inconsistent in denying continuity for bodies when they accept continuity for space. In order, then, to avoid the idea of infinite divisibility and an actually infinite number of parts in the surrounding space, they must, to be consistent, also postulate that *space* itself is composed of indivisible and unextended *points*. In that case, however, the forces filling this space cannot be extended, since they cover only *unextended points* of space; as a result the forces themselves can only be indivisible and unextended force points. Hence, everything in nature — the ultimate components of bodies, space, and force — are all indivisible and unextended points. But if this is so, then they have arrived at the position of Zeno, and all extension, even *virtual extension*, is impossible, and the arguments against Zeno apply also to their position. Their theory is thus seen to be untenable.

Continuous quantity or extension, therefore, can never be divided in such a manner that the ultimate parts are actually indivisible and unextended; division will always result in divisible and extended parts.

INFINITE MULTITUDE AND MAGNITUDE

Much of the opposition against the aristotelian concept of infinite divisibility of continuous extension is based on the contention that it involves an *infinite number of parts in a continuum*. The argument is somewhat as follows: Division results in parts; infinite divisibility must, therefore, presuppose an infinite number of parts; God, in His omnipotent power, must be able to carry out this divisibility and make the actual division; extended continuity, therefore, consists of an infinite number of parts; but an infinite number is impossible; consequently, extended continuity with an infinite divisibility is impossible. Let us examine the matter. Fundamentally, the objection rests on the impossibility of an infinite number.

By number we understand a *collection or aggregate measured by a unit*. In speaking of an 'infinite number,' it is essential to distinguish between a 'potentially infinite number' and an 'actually infinite number.' A potentially infinite number is a number which is finite and limited in itself, but is capable of being increased indefinitely, without limit. An actually infinite number is a number greater than which none can be conceived; it is incapable of increase and it cannot be exhausted by successive subtractions; it is *positively without limit in its sum of units*. This latter, the 'actually infinite number,' is in question, and we contend:

An actually infinite number is impossible.

Such a number involves a contradiction in terms, because it involves patent absurdities. Let us examine the matter practically.

Every number begins with 1; this is followed by 2, 3, 4, 5, 6, 7, 8, and so forth, until the infinite number is reached. Half of this supposedly 'infinite' number consists of odd numbers (1, 3, 5, 7, 9, 11, etc.) and half of even number (2, 4, 6, 8, 10, 12, etc.); the sum of these two series (odds plus evens) forms the infinite number. Is the odd series infinite? Obviously not; it is only half as large as the original infinite number. If it were 'infinite,' it would be equal to a number double its size, and the original number would be equal to a number half its size; that would be a contradiction. The odd series, therefore, is finite. For the same reason, the even series must be finite. Both being, singly and individually, finite, each can be exhausted by subtraction of individual units or groups of units. However, the odds plus evens form the original infinite number. Since both series can be exhausted, their sum can be exhausted. Their sum, however, is the original infinite number. Consequently, the original infinite number can be exhausted. If it can be exhausted, it is not infinite, but finite. Hence, the 'infinite' number is a 'finite' number — a contradiction in terms.

Here we spoke of an infinite number composed of single units. But numbers can also be used in groups, for example, groups of 10, and each group can be used as a unit. If an infinite number is possible, it must be possible to have an infinite number of such groups. In that case, however, we would also have an infinite number of the single units which form the group. Using groups of 10, there would be an

infinite number of single units and an infinite number of groups of 10 units. Both numbers are infinite, and yet the infinite number of single units is ten times larger than the infinite number of the groups of ten, while the infinite number of groups of 10 is ten times smaller than the infinite number of single units. We now have a smaller and a larger infinite number. The smaller number is obviously limited in comparison to the larger, yet both are infinite. The unlimited, infinite number is limited, finite — a contradiction in terms.

If an actually infinite number is possible, the *omnipotence* of God, being infinite, must be capable of making it an existing reality. God could, for instance, create an infinite number of human beings. The number of their hands, however, would be twice as large as the number of these human beings, and the number of fingers ten times as large. Evidently, by counting off the number of hands and fingers simultaneously with the number of human beings, the latter number would be exhausted before all the hands and fingers were counted. Consequently, the number of human beings, since it is exhaustible, is finite; and yet it is not finite, but infinite and therefore inexhaustible — a contradiction in terms.

Any number of practical examples, involving similar absurdities, could be multiplied. An actually infinite number is thus seen to be absurd, because it involves a contradiction in terms. The fundamental reason should be obvious: since any number, even a supposedly infinite number, is nothing but the sum of units or groups of units, *each of which is finite*, the total collection or aggregate

must itself be finite. An 'infinite number' is simply a mental fiction, an *ens rationis*, a logical or conceptual being.

An infinite magnitude is impossible.

This follows logically from the impossibility of an infinite number. Magnitude, whether of line or surface or solid, can be *measured in units* of some standard. An infinite magnitude would thus involve an actually infinite number of such units of measurement. An infinite number, however, as just pointed out, is intrinsically impossible, because it involves a contradiction in terms. Hence, an infinite magnitude is itself a contradiction in terms and, therefore, impossible.

Take a practical example. Since an infinite magnitude is infinite, it is without limits. Measuring it in kilometers, one could never exhaust its magnitude and measure it out; if one could, it would not be infinite, but finite, because one would reach its limit. Consequently, there must be an infinite number of kilometers in a magnitude of infinite extent. But there are 1000 meters in each kilometer, and a 100,000 centimeters in each kilometer. It follows, then, that the number of meters is 1000 times larger, and the number of centimeters 100,000 times larger, than the number of kilometers. In counting off the centimeters, meters, and kilometers simultaneously, one would *exhaust* the number of kilometers long before one came to the full amount of meters and centimeters. However, to exhaust and come to the end of any number, means that this number is limited and finite in its amount. The number of kilometers in an

infinite magnitude is both infinite and finite — a contradiction in terms.

‘Infinite number’ and ‘infinite magnitude’ are thus seen to be a contradiction in terms and, therefore, intrinsically impossible. They are of the same order as a ‘square circle’ and ‘wooden iron.’

The *ultimate reason* for the impossibility of an infinite number or infinite magnitude lies in the actual, positive infinity of God’s essence. Since His essence is infinite in perfection, it can be imitated by creatural beings without the possibility of ever exhausting its imitability. The number of creatural beings imitating His essence can always be *increased without limit*; in other words, the number of imitating creatures is always actually finite, but *potentially infinite*. Could the number of imitating finite creatures ever exhaust God’s imitability, God’s essence would be finite, not infinite.

Hence, too, God’s omnipotence cannot create an actually infinite number of creatures, not because of lack of power, but because of the positive infinity of the perfection and imitability of His essence. God cannot make or posit things that involve a contradiction in terms, simply because there is, under such conditions, nothing to make or posit without introducing a contradiction in Himself.

PRESENCE OF PARTS IN EXTENSION

So far we have proved that continuous extension is capable of division without limit, that it does not consist of components which are indivisible and unextended, and that

an actually infinite number is intrinsically impossible. We now come to the problem of the presence of parts in continuous extension. *If* extension is continuous, *are there parts* present in it; and, if so, *in what manner*?

The first question is easily settled. Only a simple entity, one devoid of composition, is indivisible; since it has no parts, it cannot be divided into parts. *A continuum is not simple*; it can be divided into parts. Division presupposes composition, and composition presupposes parts bound together somehow into a composite whole. Division merely breaks down the whole into its components; it does not create the components themselves. Hence, the components or parts must be in the whole or continuous extension prior to the division, so that the division can make an actual separation of them. *A continuum, therefore, possesses parts.*

The second question is more difficult to answer. Two views have been advanced. The one states that the parts of continuous extension are present prior to division *actually* and *formally as parts*. The other states that they are present, not actually and formally, but only potentially, so that there are no actual parts as such until the division is made. *Suarez* (1548—1617) and some scholastics uphold the former view; *Aristotle, St. Thomas* (1225—1274), and the majority of scholastics defend the latter. The difference between these views may possibly be merely a difference in the terminology, and not in the substance, of teaching. Hence, a clarification of terms will be necessary.

We distinguish between the *material, entitative parts* and the *actual formal parts* of a *continuum*. By ‘material’ or

‘entitative’ parts we mean the components in so far as they are realities which, though distinct from one another in their being, have no boundaries or limits marking off the one from the other, but coalesce to form a continuous and *extended whole*; the whole has boundaries, but not the material, entitative components which form the whole. A straight line, for instance, has a boundary or limit at each end; but the components or entitative parts of the line have no boundaries of their own, except the boundaries of the line as a whole. By ‘actual’ or ‘formal’ parts we mean the components in so far as these realities have boundaries or limits marking off the one from the other, with the result that not only the whole as a *whole* but also each part *as a part* has boundaries. A house, for example, is a whole with distinct boundaries as a house; but each brick, piece of wood, nail, pipe, wire, fixture, etc., also has its own boundaries. A thing with material, entitative parts, such as a line, is actually and intrinsically a single unit, and its parts become actual and formal parts only after division, as when we divide a line in two. A thing with actual, formal parts, such as a house, is a collection of multiple units arranged to form an extrinsic whole, and the division between part and part is already present. In the case of material, entitative parts, it is impossible to designate the beginning and end (the boundaries) of the parts and to make definite measurements of them; in the case of actual, formal parts, this designation and measurement can be made.

We contend that in continuous extension the components are *material, entitative parts*, but not *actual, formal parts*.

Bearing the above definitions and explanations in mind, it should be obvious that a continuum contains parts distinct from other parts, at least so far as their reality is concerned. Continuous extension is not a simple, but a composite, entity; actual division can produce in it actual, formal parts, as experience proves when we divide a line, a surface, or a solid. But if division can produce actual, formal parts in a thing which has continuous extension, the material, entitative reality of these parts must be present before the division. Division does not produce the 'reality' of these parts, but merely separates them and gives them definite boundaries.

These parts, however, are *not present* in continuous extension as *actual, formal parts*, i.e., with definite boundaries distinguishing one part from another. If these parts were present with definite boundaries, actually and formally *as parts* and not merely as realities, they could be numbered, and this number would of necessity be either finite or infinite. This number cannot be a finite number, because continuous extension, as we have shown, is infinitely divisible, and infinite divisibility is impossible with regard to a thing that possesses only a finite number of parts. This number cannot be infinite, because an infinite number is a contradiction in terms. Moreover, if the parts in continuous extension were present actually and formally as parts, each part would be delimited from every other part by its own boundaries, because that is what is meant by 'actual' and 'formal' parts. In that case, however, their boundaries would not coalesce into one; at best, parts could only touch other parts at their external boundaries. They

would then be *contiguous*, but *not continuous*. Continuity would thus be destroyed. Consequently, if continuous extension is possible at all, its components cannot be 'actual, formal parts'; formal parts are only potentially present and become 'formal parts' through actual division.

EXISTENCE OF CONTINUOUS EXTENSION

Up to this point, our examination of continuous extension has been more or less abstract; that is to say, we have considered it from the standpoint of its *concept*, as we think and speak of it, without any definite investigation whether continuous extension has *existence in nature*. This naturally raises the question: Has the concept of continuous extension *objective validity*? In other words: Do *objects exist* in nature possessing continuous extension?

In pre-scientific days practically no one doubted the existence of continuous extension in physical objects. With the advancement of science, however, it soon became clear that continuity in bodies was more apparent than real. The *atomic theory* disclaimed any real continuity in molar bodies, such as a lump of gold or carbon; large bodies consist of molecules and atoms, and these have definite weights and shapes, i.e., limits and boundaries which do not coalesce, strictly speaking, into continuous extension. Recent science, with its investigations into electrons, protons, etc., is even more emphatic on this point; even the atom is not a continuous whole, but consists of discrete, separate particles. However, as we shall see, the findings of

modern science do not really touch the problem of actual continuity in any fundamental way.

Philosophically, the existence of continuous extension has been attacked on different grounds. That physical bodies should be a continuous whole, without actual, formal parts, seemed to some philosophers a mystery beyond comprehension. We have previously mentioned that certain philosophers attempted to explain extension by assuming that it consisted ultimately of indivisible and unextended parts, with or without virtual extension. Modern philosophic opposition to the existence of continuous extension arises mainly from *epistemological* difficulties, i.e., from difficulties concerning the validity of man's knowledge act. *René Descartes* (1596—1650) proposed the doctrine that the essence of the soul is thought and the essence of matter is extension. This doctrine placed an impassable gulf between the body and soul in man; a real contact and union between such diverse entities seemed impossible. In consequence, knowledge was considered to be a purely mind-made product. *Phenomenalism and idealism* soon dominated the field of philosophy. It became the general conviction in non-scholastic circles that the mind could not possibly reach the outside world directly. True, the outside world somehow makes an impression on the mind, and the mind reacts by forming certain images of this world; but whether our knowledge of the external world, as thus acquired, truly pictures the world as it exists in itself, is a highly debatable question. Most modern theories of knowledge accept the view that the external world, as it is in and for itself, is unknown and unknowable by us; at best, our knowledge is

only symbolic and representative, not intuitive and presentative. Our knowledge of the world has only *subjective value*. It is not within the province of cosmology to explain all the confusing and conflicting theories of knowledge which have arisen in modern times; their evaluation belongs to *epistemology*.⁴

We are *presentative realists*. We are convinced that we possess, in many ways, an intuitive, direct knowledge of the physical world around us, especially as regards the primary qualities of physical objects, namely, extension, shape, motion, rest.⁵ We assume, in this connection, the essential validity of our consciousness and sense perception. Following this assumption, we maintain that *continuous extension* of physical bodies, at least in their ultimate components, is a fact of nature. According to the present status of scientific knowledge, these ultimate components are electrons, protons, and neutrons, etc. As a matter of fact, these particles may themselves be the product of composition; we do not know. Since we have no evidence of any particles more minute than these, we accept them provisionally as the physical ultimates of ponderable matter. And now to the *proof*.

Our consciousness testifies to the fact that our senses, especially sight and touch, *perceive extension* in two and three dimensions. Unless we wish to accept the complete subjectivism of all knowledge, we must admit that *physical objects* are the cause of this perception. But if the ultimate components of physical bodies are absolutely indivisible and unextended, so that they are not 'continuous' in their extension, nothing in this world would be actually extended.

Under such circumstances, however, it would be impossible for bodies to produce the perception of extension in our sense organs. The objects being unextended and the sense organs being unextended, objects could never appear as extended, whether objectively or subjectively; if they did, all knowledge is falsified, and skepticism is the inevitable outcome. That, however, we cannot admit. Hence, the ultimate components of bodies must be really and continuously extended. It will not save the situation to assume that the *forces* of the ultimate components are extended while the components themselves are unextended. Forces are qualities, and they cannot exist except in a material substrate as their subject. If the subject is not extended, the force cannot be extended; and if the force is extended, the subject is extended. But the subject of force is the particle of matter which is the ultimate component of the physical body (electron, proton, etc.). Consequently, the ultimate components of physical bodies must be really extended, i.e., continuous in three dimensions. Hence, continuous extension exists.

Science measures the electrons, protons, and other subatomic particles according to their weight, linear dimensions, etc. So far as science is concerned, they occupy definite amounts of space. This would be impossible, if these particles (or their ultimate components) were not genuinely extended. If the entire picture of the world, as given to us by science, is false, we must despair of knowledge. Hence, we must accept extension as a universal property of physical bodies in their ultimate components. Moreover, the phenomena observed in the *bombardment of atoms* by

subatomic particles are inexplicable except on the supposition that these particles actually collide and, possessing *impenetrability*, tend to hinder each other from occupying the same space. However, if they (or their ultimate components) were unextended mass points or force points, they could neither collide nor stop interpenetration. Consequently, they must have extension. Only *continuous* extension is real extension in the meaning of these experiments, for the reason that otherwise physical bodies would ultimately consist of nothing but contiguous points without continuous extension, and *contiguous points* cannot occupy definite portions of space.

These considerations of a philosophic and scientific character compel us to accept continuous extension as objectively present in nature.

THE FORMAL EFFECT OF QUANTITY

By the *formal effect of quantity* we understand that particular character, determination, or 'form' which a body receives primarily and specifically because it is endowed with quantity; it is the immediate and proper effect which quantity communicates to the bodily substance which it modifies by its presence in it. There are a number of properties which might come under this heading: divisibility, impenetrability, measurability, external extension, and internal extension.

The concepts 'external extension' and 'internal extension' need some explanation. *External* extension is that extension of body in virtue of which its parts are

distinct with reference to *place and space*, so that one part is in one part of space and another part in a different part of space, each excluding the other from the place and space it occupies. This is also called 'local' or 'circumscriptive' extension. *Internal* extension is that extension of a body in virtue of which its parts have a definite *position and order among themselves* and in reference to the *body as a whole*, regardless of the place or space which they occupy. It also goes by the name of 'sital' or 'positional' extension. That a body has three dimensions, measurable in centimeters, etc., is due to its external extension; it possesses volume and shape. However, even if all dimensions were removed, the order of the parts of a body due to its internal extension would still remain the same; the hand of the human body, for example, would be connected to the forearm, the forearm to the upper arm, and the upper arm to the shoulder and thereby to the torso, and there would be no confusion of these parts among themselves and in reference to the whole body.

Each of the properties mentioned has been advocated as the formal effect of quantity. *Measurability* and *impenetrability* cannot be the primary and proper effect of quantity, because they are relative in character, presupposing other bodies, while quantity is an *absolute* property which affects a body *in itself*, even if it were the only body in existence. *Divisibility* is not the formal effect of quantity in a body, because a body must have extensive parts alongside parts among themselves, before they can be separated through division. That leaves either external or internal extension as the formal effect of quantity. *External*

extension is not the formal effect, because a body must have parts which possess a definite position relative to each other and to the whole body, before they can be spread out or distributed in space. Hence, by a process of elimination we arrive at the conclusion that *internal extension* is the formal effect of quantity.

And in truth, *internal extension*, or the position and order of parts in their relation to each other and to the whole, seems definitely to be the one property of quantity which is the *root* and *matrix* of all other properties commonly associated with quantity. Because of this property, bodies have the natural aptitude and exigency to be distributed in space, so as to be externally or locally extended; and because bodies have local extension, they also are measurable, impenetrable, and divisible. Hence, internal extension is the primary and specific determination which is the immediate and proper effect communicated by quantity to a body; and that is what is meant by the 'formal effect' of quantity. That bodies are *material* substances, makes them to be 'bodies'; that they have parts with a definite *position and order* among themselves, makes them to be 'quantified.'

The question has been raised whether *external extension* could, through the omnipotent power of God, be *separated* from a material substance, leaving internal extension intact but depriving the body of its threefold dimensions in space. Philosophically speaking, there is no contradiction in the view, because internal extension would still have the *natural aptitude* and *exigency* for external

extension, even though actual external extension would be missing. That is all philosophy can say on the question.

Such, then, is the nature and character of quantity. It affects the material substance directly and is its most fundamental attribute.

SUMMARY OF CHAPTER VI

All bodies are characterized by quantity and extension.

1. *Experience of Quantity and Extension.* Bodies appear in three dimensions. Our knowledge of this is based on the commonplace and scientific observation of our senses. There is also quantity in the degrees in which physical realities appear. We also observe quantity in the *number* of concrete objects.

2. *Concept of Quantity and Extension.* Aristotle defines a quantum as that which can be divided into its inherent components, each of which (after division) is a single and complete whole. The whole is undivided, but divisible; actually one, but potentially multiple.

3. *Kinds of Quantity and Extension. Continuous and Discontinuous Quantity.* It is 'continuous,' when it is uninterrupted in its being, so that the components within it are united by common limits or boundaries. It is 'discontinuous' or 'discrete' when it consists of components, each of which is an entity for itself, with its own complete limits or boundaries. A discontinuous quantity is either 'contiguous' or 'separate': 'contiguous,' when the components are in contact at their boundaries; 'separate,' when the components are at a distance from one another and are united by some intermediate reality.

Dimensive, Intensive, Successive Quantity. 'Dimensive' quantity is one of extension, magnitude. 'Intensive' quantity is one of degrees. 'Successive' quantity is one whose components follow one another in sequence. Quantity in

general is that property of a thing by virtue of which measure or number or division is applicable to it.

4. *Divisibility of a Continuum.* Continuous quantity, purely as such, is infinitely divisible. Only if division could reach the indivisible, unextended mathematical points, would there be a limit to divisibility. But if unextended points were the components of continuous extension, there never could be a continuum, because no sum of unextended units can produce extension. Hence, a continuous quantity must ultimately consist of extended components, and divisibility can take place without limit, because it can never reach unextended points. If Zeno were correct, change of speed and even motion itself would be impossible. In *virtual* extension, space is either continuous, and then its advocates are inconsistent, or it consists of unextended points, and then all continuity is destroyed.

5. *In finite Multitude and Magnitude.* An infinite number is a contradiction in terms, because any number can be exhausted; it has limits. Some supposedly infinite numbers would be larger or smaller than other 'infinite' numbers; this is a contradiction in terms. Magnitude cannot be infinite in extent; because it can be measured by units, and units can be numbered; hence, infinite magnitude would involve the absurdity of an 'infinite number.'

6. *Presence of Parts in Extension.* Continuous quantity, being capable of division, cannot be simple, but must be composite; hence, it must consist of material, entitative components or parts in some manner. It cannot, however, consist of actual parts, otherwise division has already taken place, and there would not be 'continuous' extension; the

actual parts would be merely 'contiguous.' Hence, the parts can only be *potential* parts.

7. *Existence of Continuous Extension.* We perceive extension in three dimensions. If all bodies consisted ultimately of unextended mass points or force points or both, there would be no extension in nature and bodies could not be perceived as extended. *Science* measures electrons, protons, etc.; hence, they must be extended. The bombardment of atoms shows *impenetrability*; but impenetrability would be impossible for unextended points.

8. *Formal Effect of Quantity.* This seems to be *internal* (situal, positional) *extension*, namely, that extension of a body in virtue of which its parts have a definite position and order among themselves and in reference to the body as a whole. External or local extension follows internal extension as a natural aptitude and exigency; measurability, impenetrability, and divisibility are a natural consequence of external and internal extension. Absolutely speaking, there is no contradiction in the view that external extension can be separated from material substance.

Chapter 7

PLACE AND SPACE

IN DISCUSSING QUANTITY AND EXTENSION, IS WAS FOUND unavoidable on a few occasions to mention *place and space*. Quantified and extended objects, as they exist in physical nature, have a 'place' and occupy 'space.' 'Place' and 'space' are practically inseparable ideas and terms. Everyone uses these terms in daily conversation, and everyone attaches a fairly uniform meaning to them. However, if pressed for an accurate explanation, few people are capable of giving more than a vague and shadowy definition of 'place' and 'space'; even philosophers find it difficult to fix their exact meaning. Since they play such a prominent part in our mental vocabulary and are so closely connected with all physical bodies and with the universe at large, the cosmologist must seek to understand these concepts in their more fundamental aspects and determine their ultimate essence.

COMMON MEANING OF PLACE AND SPACE

In attempting to arrive at the exact content of concepts such as 'place' and 'space,' we must consider the *common*

usage of the terms. People say that persons and things are *at* or *in* a place; they *arrive* at a place or *leave* a place; they go or are brought *from* one place *to* another place; they are *in* place or *out of* place; and so forth. These and similar expressions plainly indicate that, in their estimation, a 'place' is that which objects change when they *move*, so that one 'place' is at the starting point of the motion and another at the stopping point; and such motion is therefore called 'local' motion. No one ever speaks of a 'place' as if it were or could be in motion itself; on the contrary, when compared to motion, a 'place' is conceived as something which is *stationary* and *immobile*. Sometimes the term is taken in a looser sense, as when we say that a vase is on the table, the table in the room, the room in the house, the house in the city, etc. At other times the term is used in a more restricted sense, and then we mean the immediate locality which corresponds to the volume of the object as such.

Space has a wider signification than 'place.' 'Places' are, generally speaking, *portions* of space; they are *in* space, while 'space' is never spoken of as being in any particular 'place.' Bodies move *in* and *through* space, when they go from place to place; and by the very fact that they are in a definite 'place' they occupy 'space.' Space is also considered to be stationary and immobile, so that all bodies have their motion in space, while space itself does not move with the moving objects. Like place,' space has *three dimensions*, length, depth, and width. We speak of large and small space, wide and narrow space, empty and filled

space, limited and infinite space, parts of space and all space, actual space and possible space.

In whatever way, however, we use the term 'place' and space,' they are thought of, or rather imagined, as *receptacles* or *containers* of extended bodies. Both are thus conceived as being something distinct from the bodies which are in them.

PHILOSOPHIC CONCEPT OF PLACE

'Place' indicates where an object is. Basing our analysis of the term 'place' on its usage, we must distinguish between internal and external place.

The *internal place* of a body is the amount of space contained within the boundaries of the *outside surface* of this body, considered as the receptacle of the body's entire volume. Taken in this absolute sense, every body taken singly and the universe taken as a whole can be said to have a definite place. Even if only a single body were in existence, it would have a 'place' in space, due to its presence within the boundaries of its own limiting surface.

The *external place* of a body is the *surface* of the object or objects *immediately enveloping* this body, considered as the receptacle of the body's entire volume. In this relative sense, the 'place' of a body is determined, not by the volume of the body itself, but by the concave surface of the object or objects which are in direct contact with it and completely surround it on all sides. External place always presupposes other bodies in existence together with the located body itself; these other bodies give it 'place.'

Aristotle defines external place as “the first (or immediate) immobile limit (or surface) of that which contains a body.”¹ Here the ‘limit’ or ‘surface’ of the containing body is considered *formally as a surface* corresponding to definite portions of space, and not materially as consisting of a certain kind of matter (gold, paper, wood, air, water, etc.). An air bubble, for example, in a pane of glass has a ‘place’ there in so far as it is completely surrounded by the concave surface of the glass enveloping it. This surface of the glass corresponds to definite portions of space, when the glass is stationary. If, however, the pane of glass, and the air bubble with it, are moved, let us say, two feet to the side, the concave surface of glass surrounding the air bubble will now correspond to *different* portions of space. *Materially*, the surface enveloping the air bubble has not changed, because it is still the same surface of glass; *formally*, however, precisely as a locating surface, it has changed, because it no longer corresponds to the same portions of space as it did before it was moved: the ‘place’ of the air bubble has changed, even though the material surface of the glass is still the same. On the other hand, if water could be substituted for the glass leaving the air bubble stationary, the air bubble would still be in the same ‘place’; the ‘material’ surface would have changed from glass to water, but the ‘formal’ surface corresponding to definite portions of space would have remained intact throughout the process. Similarly, a fish, stationary in moving water, would remain in the same ‘place,’ because the surrounding surface of water, formally as a surface, does not change its relation to space, even though the

material surface of the water be constantly changing; reversely, a fish, traveling with the water at identical speed, so that the material surface of the water does not change relative to the fish, changes its 'place,' because the surface of the water, formally as a surface relative to space, does not remain the same as both water and fish move along. All this follows from the notion of 'place' and 'space' as something *stationary* and *immobile*. External place, as explained so far, is the *proper* place of a body.

There is, however, also a *common external place* of bodies, and by this we mean, not the immediately contacting surface which envelops the body, but the *general position* of a body with respect to other bodies at *some distance* from it. There is always some body which serves as an immobile point of reference which fixes the spatial relations of the localized body. A man, for example, may stand still on a moving ship. Taking the ship itself as a fixed point of reference, he can be said to have a definite 'place' on the ship; taking the shore, however, as the point of reference, he moves with the ship and changes his 'place' from moment to moment. Things, therefore, may move and not move at the same time, with respect to two different points of reference, without contradiction; but this can never be the case with respect to the same point of reference, for that would be a contradiction in terms. In this manner, anything in a room has a 'place' in the room; anything on the earth has a 'place' on the earth, even though the earth (and with it the room) moves around the sun. The earth is a fixed point of reference for localizing all objects in it, on it, and above it; the sun is a fixed point of

reference for localizing all objects in the solar system. Whether there is an immobile point or axis in the universe which could fix the spatial relations of all objects in it, scientists have so far been unable to discover.

UBICATION

If 'place' indicates 'where' an object is, the *presence* of an object in a place is its *whereness* or *ubication* (Lat., *ubi*, where), in so far as an object is precisely in one place rather than in another. We distinguish a threefold presence of beings in a certain place: circumscriptive, definitive, and repletive.

A *circumscriptive* presence is the presence of a corporeal extended substance in such a manner that it has parts outside parts in the place where it is. This is also called 'quantitative' presence. All bodies in the universe, whether they consist of ponderable or imponderable matter, have this sort of presence 'in a place'; they fill extended space with their own extended reality.

A *definitive* presence is the presence of a spatially unextended substance in such a manner that it can exercise its activity only within certain limits of space. Such is the presence of spiritual beings in the universe; and such, too, is the presence of the immaterial soul of man within the limits of his body as its animating principle. Spirits and human souls have no parts outside parts in their being, because they are simple entities, and thus they can have no circumscriptive or quantitative presence in space; but their

activity is limited to certain restricted areas of space, so that they are 'localized' and are not present everywhere.

A *repletive* presence is the presence of a spatially unextended substance in all space, past, present, and future. This is the presence of God in all things; He is 'everywhere.' It is also called 'ubiquity,' and the infinite perfection which is the foundation for this ubiquity is His 'immensity.' God not only creates things, but His repletive presence within them is necessary for the conservation of their being; were He to withdraw His conserving presence, they would instantaneously drop back into the nothingness from which His creative *fiat* called them forth.

PHILOSOPHIC CONCEPT OF SPACE

In general, as was mentioned previously, *space* is the *three-dimensional container or receptacle of all extended material substances*. Space, as we conceive it, is a peculiar thing. It not only embraces the actual universe, but extends beyond it in all directions as some sort of limitless, infinite, empty reality. If God created a thousand more universes, space would be there to receive them; it is inexhaustible in its receiving capacity. Before the universe was made, space was there to receive it; and if the universe were annihilated, space would remain, ready to receive other universes of any imaginable extent at any future time. Space is thus conceived as an *infinite* and *eternal* sort of entity. What are we to think, from a philosophical standpoint, of this thing called 'space'?

Philosophers have suffered considerable vexation in attempting to arrive at a correct notion of space. Among the ancients, *Democritus* (born about 460 B.C.) and *Epicurus* (341 or 342—270 B.C.) maintained that space is an *actual reality*, existing in itself and prior to all bodies. *Gassendi* (1592—1655) taught a similar doctrine; space is neither a substance nor an accident, but a unique entity, eternal, unchangeable, impervious to the senses, distinct and different in its being from God and from corporeal things.

Newton (1642—1727), *Clarke* (1675—1729), *Fénelon* (1651—1715), and *Bayma* (1816—1892) identified space with the *immensity* of God, because our notion of space implies that it is something infinite and that it had existence before the world was made. *Lessius* (1554—1623) and others identified it with the infinity of God, because only God's infinity can be said to be boundless, to exist before creation, and to contain all created things. Pantheists, quite naturally, consider infinite space as a mode of the *Absolute*.

Kant and his followers considered 'space' to be a *purely subjective sense form*. Objects exist in the physical world outside the mind; they are noumena, things-in-themselves. We cannot know what these things-in-themselves really are. They make impressions on our senses, and the senses react to these impressions with images. These images are clothed by the mind with the intuitions of 'space' and 'time.' In consequence of this, all objects *appear* to us as three-dimensional, as spatial. But spatial dimensions are not objective attributes of the objects themselves in nature. 'Space' and 'time' are subjective, *a priori*, innate *sense forms*, present in the mind before all perception, making

perception possible; they are like molds of the mind, into which the chaotic manifold of outer impressions is cast, appearing after the perception process as affected by 'space' and 'time.' The concept of 'space,' therefore, is a mental construct without any ground or foundation in the objects themselves as they exist in nature. Kant's theory has influenced many modern theories of knowledge. Our knowledge, according to these theories, is *causally produced* by outside objects; whether, however, there is an actual correspondence between our knowledge and the things as they are in themselves, it is impossible to determine. The general view tends toward the opinion that our representation of things is more or less symbolic in character. Obviously, then, 'space' is more *phenomenal* than real.

The modern theory of *Space-Time*, as advocated by *S. Alexander* and others, considers Space-Time to be the stuff and matrix out of which all things and events emerge and evolve. The theory will be treated in the chapter on 'time.'

Leibnitz defended the view that 'place' and 'space' consist in nothing but the *relation* of objects toward one another. *Descartes* identified space with the extended corporeal substance, the difference between them being merely a difference in the mode of conception; in itself, the extension which constitutes space is the same as that which constitutes a body. *Balmes* (1810—1848) was of the opinion that space is the concrete extension of existing bodies.

According to *Henri Bergson*, the world is an endless becoming. There are only actions, not things, in the world; even the atom is simply a view of the mind. The divisibility

of matter is only apparent, because it is the mind which divides the continuity of the extended. This is done by throwing a 'network' beneath the continuity of sensible qualities, and this wholly ideal diagram of arbitrary and infinite divisibility is what Bergson terms *homogeneous space*. Space is thus nothing more than an *ideal scheme* or *symbol* appended to matter, to render the latter divisible by the mind according to our actions and needs.

Scholastics, whom we follow in this question, view 'space,' as we conceive it, not as an actual being, but as a mental abstraction based on the extended reality of bodies. They distinguish between three kinds of space: real, possible, and absolute. *Real* space is the *space occupied* by existing three-dimensional bodies. Thus, the space occupied by ponderable and imponderable matter in our universe is 'real' space. If there are other existing universes besides our own, then the space occupied by them is also 'real' space. Since infinite magnitude is impossible, 'real' space is limited in extent, no matter how many universes there may be. And since an actually infinite number is impossible, there can be no actually infinite number of universes in existence; the omnipotence of God can create still more universes. It follows, therefore, that 'real' space is *capable of being increased indefinitely* through the creation of new universes. Hence, more real space is possible than that which is actually filled by presently existing bodies, and this 'possible' space is conceived as extending without limit beyond the confines of the existing universe or universes. Possible or ideal space is thus seen to be space *unoccupied* but *occupiable* by extended bodies, in so far as more bodies

could be created to fill space. *Absolute* space, then, is the *sum of real and possible (ideal) space considered as one*. It makes no difference in our concept of 'space,' whether it is occupied or not. It is simply 'space' in three dimensions extending infinitely in all directions, and that from eternity to eternity. Space, considered as one or a whole, is partly occupied and partly unoccupied; but all of it is 'space.' Since our concepts are usually accompanied by images of the imagination, we also picture absolute space as an immense container, something like an immense box; this is *imaginary space*.

According to the scholastics, 'space,' *as we conceive it*, cannot be an actually existing reality, infinite in extent and eternal in duration, the receptacle of all bodies actual and possible. As such, it has existence only as a concept of the mind. Yet, it is not a purely mental fiction, like a 'square circle.' It is. an *abstraction* of the mind, derived from the extension of existing bodies, with a foundation, or ground, or reason, in this very extension of bodies. Hence, 'space' as we conceive it is a *conceptual being with a foundation in physical nature (ens rationis cum fundamento in re)*.

We contend that the scholastic view of 'space' is the correct one. And now for the proofs.

SPACE NOT A REAL BEING

Space, as we conceive it, is the three-dimensional *receptacle* of all extended bodies, so that the parts of these bodies are commensurate with the corresponding parts of space. Furthermore, space is conceived as a positive sort of

entity which has always been present in the past and will always be present in the future, to receive any extended body which God in His omnipotence may create; and since there is no limit in the past or future to the creative ability of God's omnipotence, space must have, if it is a real being, a *positive eternity*. Finally, since there is no limit to the number of worlds which God's omnipotence can create, and since space must have the necessary extension to receive these worlds, space, if it is a real being, must have a *positive infinity* in extent.

Space, as such a real being, is impossible. It cannot be *infinite* and *eternal*, because only God is infinite and eternal, and space is not God. That space is not God, is obvious, for God has no parts outside parts in three dimensions as space is conceived to have.

Again, space, conceived as a three-dimensional receptacle of *limitless extent*, is impossible. That would involve an infinite magnitude and an infinite number of parts in its being. But an infinite magnitude and an infinite number are a contradiction in terms. Hence, such a being cannot exist.

Furthermore, if space were a real and existing being in the physical order, it would of necessity exist either for itself and in itself or it would exist in another; in the first case it would be a physical 'substance' and in the second case a physical 'accident.' But space, as conceived by us, can be neither a *substance* nor an *accident*. If it were a substance, it must be either a spiritual or a material substance. It cannot be a spiritual substance, because a spiritual substance is a simple entity which has no parts; space,

however, has parts, and these parts are extended. Hence, it would be an extended material substance. But an extended material substance is a 'body.' Space, however, is conceived or imagined as the *receptacle* of all 'bodies,' not as a 'body' itself. There must, then, be a second space to contain the 'body' of this first space; and, since this second space is also a bodily substance, a third space is required to contain the second space; and a fourth is required for the third; and so on, through an *infinite regress*. No one, however, conceives space as requiring another space to receive and contain it. Consequently, space cannot be a 'substance.' Neither can space be an 'accident.' If it were, it would be an extended, three-dimensional accident, demanding an extended, three-dimensional substance in which to exist. But such a substance, as was just shown, must be a corporeal substance, a 'body.' And then the absurdity of space within space in infinite regress would result. Space, therefore, cannot be either a substance or an accident. However, if it exists, it must be either the one or the other; and since it can be neither, it follows that space is not a real, existing being.

From this it should be clear that it is an error to identify space with the *infinity* or *immensity* of God. These attributes of God are infinite perfections, one with the essence of God. God's essence, however, has no parts, much less 'extended' parts. God is a pure spirit, while space is never conceived as a 'spirit' with intelligence, free will, and creative power. God is infinite actuality and activity, while space is conceived as an inert, stationary, immobile thing. This much, however, can be admitted as true: God's infinite

power of creating possible beings and His limitless power to be present in all creatural beings are the *ultimate* reason why we *conceive* space to be infinite in extent and eternal in duration. But that is no justification for *identifying* space with the infinity or immensity of God.

Nor is it correct to identify space with the *external relations* of bodies, as Leibnitz did. Space is conceived by us as the 'receptacle' of bodies, not as their 'relations.' Space is either filled or empty; but no one speaks of filled or empty relations. Space extends far beyond the confines of the universe, where there are no bodies and where, consequently, there can be no 'relations' between bodies.

Similarly, it is erroneous to identify space entirely with *extended material substance*, as Descartes assumed. Extended material substances cannot be said to be filled or empty, as space is said to be. Extended material substances are restricted to the limited extent of the universe, but space extends beyond the universe. Then, too, space is conceived as being the 'receptacle' of extended material substances, not as the substances themselves. Finally, space is stationary and immobile, while extended bodies move in and through space. It is thus seen that our concepts of 'space' and of 'extended material substances' are not at all identical. The same arguments apply to Balme's view. These considerations compel us to draw the conclusion that 'space,' as we conceive it, is not a real being existing as such.

SPACE NOT A PURELY MENTAL BEING

By a 'purely mental, or conceptual, being' we understand something that has no existence and no objective value except *in and for the mind*. The content of the concept of such a being cannot be found anywhere in nature; nor is there anything in nature which could serve as a foundation or ground for such a being, so that the mind might arrive at its concept through a process of abstraction. Subjects and predicates of sentences, grammatical parts of speech, argumentations and their laws of inferences, and so on, are purely mental (conceptual) beings; so, too, are contradictory concepts treated by the mind as if they were entities, such as a 'square circle,' 'wooden iron,' etc. *Kant* and his followers maintain that 'space' is a purely mental form, present in the mind antecedent to all perception and experience, with nothing in nature to account for the concept. This, we claim, is not true; it is not a purely mental construct, but has a *foundation* in the reality of physical bodies and as such has *objective value*.

In order to substantiate his contention that 'space' is a pure intuition of the sense faculty, the product of an *a priori sense form*, *Kant* would have to prove that the notion of 'space' is antecedently present in the mind, prior to all experience, as a subjective condition of sense perception, and not as the result of a mental abstraction or deduction following the perception of extended objects; and he would also have to prove that 'space' is an intuition of sensibility and not a concept of the intellect. *Kant* assumes all this, basing his assumption on the antithesis between mind and matter, introduced by *Descartes* into the problem of human knowledge. That is an epistemological problem which does

not concern us here. Kant's assumption, however, that 'space' is an *intuition of the sense faculty*, is unwarranted and erroneous. 'Space,' as we conceive it, is something unlimited in extension and duration; and no sense faculty, being limited itself, can perceive or imagine such a thing. Only the *intellect* can have a *concept* of an unlimited reality. Hence, our notion of 'space' is a 'concept,' not an intuition of sensibility. Again, the assumption that 'space' is the result of an innate, subjective, a priori sense form, antecedently present in the mind prior to all experience and making perception possible, is radical and arbitrary, because no one is conscious of anything present in the mind prior to all experience. On the contrary, our consciousness testifies to the fact that all our knowledge begins with *experience*, and our experience begins with the perception of the actual world of concrete things. It is a matter of plain consciousness that our senses and our mind are *passively influenced* in their operations when perceiving the external world; 'extension' and 'space,' therefore, are not a purely subjective product of our mental operations. We cannot, for example, change the dimensions of our body or of our room or of a building to suit our fancy; they force themselves upon our senses and remain what they are, independent of our sense faculties and of our mind.

'Extension' and 'space,' therefore, are derived primarily from the *objects* and not from the perceiving subject.

Bergson's view on space is entirely *subjectivistic*. His monism destroys all distinction between ourselves and the world and between the things of the world among themselves. The world thus loses all objective reality

(although Bergson claims the world to be real) and becomes a mental illusion. This is contrary to common sense and science.

Science, when not distorted by philosophical theories, gives *experimental proof* that bodies exist, have measurable extension in three dimensions, and move with definite velocities from place to place. Everyday experience is entirely in accord with this verdict of science. The world is real, not an imaginary or idealistic construct of the mind. Unless, then, we wish to nullify all the findings of physics, chemistry, and astronomy, we must accept *extended and moving bodies* as an established fact. But the concept of 'space' is inescapably connected with, and related to, extended and moving bodies as the 'receptacle' in which they exist and move. It is an easy step for the mind to pass from extended and moving bodies to the concept of some sort of a 'receptacle' in which these realities are present. That, however, is precisely what we conceive 'space' to be. To say, then, as Kant and his followers do, that 'space' is a purely subjective product without any foundation in physical things, is contrary to experience and reason. If Kant's theory of space were correct, all genuine science of the physical world would be impossible and superfluous.

THE TRUE NATURE OF SPACE

So far we have been mainly concerned in pointing out what 'space' *is not*; now we are in a position to state what 'space' really *is*.

We conceive 'space' as some sort of *being*. Now, as a being, it must either exist outside the mind and independent of it, or it must exist in the mind and dependent on it. But space, as we have proved, is not a real being which exists outside, and independent of, the mind. If it were, it would perforce be either an actual receptacle of bodies, or the immensity or infinity of God, or the extended substance of bodies, or the physical extension of bodies, or the relation between bodies. We have, however, shown that space can be none of these things. Hence, it must be a being which exists *in the mind* and dependent on it, i.e., a mental, or *conceptual entity (ens rationis)*. As a conceptual being, however, it must be either a purely mental and subjective being without a foundation in physical reality, or it must be a mental being with a foundation in physical reality. It is not the first of these alternatives, as was seen when treating of Kant's theory of space. Hence, space must be a mental, or conceptual entity *with a foundation in physical reality (ens rationis cum fundamento in re)*. In other words, 'space cannot exist as *we conceive it*; in that respect it is a product of the mind. But there is a *reason* or foundation in the things of nature which justifies us in forming such a concept of 'space,' *as if* it had existence outside the mind; that saves it from being a purely mental and subjective entity. Space thus has objective value, even though our manner of conceiving it is subjective.

An *analysis* of how we arrive at the idea of 'space' will make this clearer. From earliest infancy we perceive objects. They are extended, and soon we advert to the fact that they consist of different kinds of material, have

different shapes and sizes, and have length, width, and height. Eventually we become aware of one important item of information: no matter what the material, size, and shape of the various bodies may be, all have one feature in common, namely, *extension in three dimensions*. Through a process of mental abstraction, by prescinding from all material, shape, and size and by fixing its attention solely upon the dimensions of bodies, the mind forms the concept of extension alone, simply as extension, neglecting and putting aside all other features. This is now *abstract extension*. The mind also perceives that one object 'contains' the other: the tumbler contains the water, the kitchen contains the tumbler, the house contains the kitchen, the city contains the house, the countryside contains the city, the earth contains the countryside, the universe contains the earth. Prescinding from all the different types of containers or receptacles, the mind forms the concept of an extended receptacle for all bodies. This is *abstract extension* considered as a *receptacle* for all bodies. This something conceived as the abstract receptacle of existing bodies, is called *space*, real or filled space. Besides these actually existing bodies, the mind is aware that there is room for more bodies, for possible bodies; and this *possibility* of more bodies extends indefinitely beyond the limits of the present universe, in the past, present, and future. This is *possible* or *ideal* space. Combining the two types of space, real (filled) and ideal (possible), the mind conceives absolute space in the abstract as a huge receptacle of immense extension and eternal duration, with the capacity of receiving and containing bodies of unlimited

extension at any time in the past, present, or future. It is in this manner that the human mind arrives at the concept of *space as abstract extension considered as a receptacle for bodies*. Obviously, space so conceived is an abstract reality which exists only in the mind and cannot exist as such in nature.

Summarizing this entire discussion on the nature of space, we argue as follows. Three-dimensional extension which ignores the material, size, and shape of bodies, considering merely extension as such, is abstract extension. But space is three-dimensional extension conceived in this manner. Therefore, *space is abstract extension*. That which receives and contains bodies is the 'receptacle' of bodies. Since space receives and contains all bodies, actual and possible, past, present, and future, space is abstract extension conceived as the *receptacle of all bodies*, unlimited in extension and eternal in duration. As an entity, such a being cannot exist in nature; if it exists at all, it can exist only in the mind as a concept. But a being which exists only in the mind is a mental, or conceptual, being. Consequently, space, as we conceive it, is only a *conceptual entity*, or *mental being*, in the mind. A conceptual being, however, which is present in the mind through a process of abstraction from physical extension in nature, is not a purely mental product, but has a foundation in the extension of physical things outside the mind. Hence, space is a logical, or conceptual, or mental, entity, with a foundation in real things outside the mind. We thus arrive at the final conclusion: *Space is abstract extension, considered as the receptacle of bodies, and as such it is a*

conceptual (mental, logical) being with a foundation in real things. As the scholastics put it: it is an *ens rationis cum fundamento in re*. That is the true nature of 'space.'

VACUA

Closely related to the notion of space is the concept of a vacuum, namely, the total absence of a material, three-dimensional substance in the universe.

Physicists often speak of a 'vacuum.' By this they mean the inside space of a closed vessel, exhausted of gas to a high degree; for example, the inside of an electric-light bulb or of an X-ray tube is said to be a 'vacuum.' In using this term, however, they do not really contend that every vestige of gas has been extracted from the container; the amount remaining, though, is so small, that for all practical purposes of experimentation it is negligible and can be considered as totally absent. When cosmologists speak of a 'vacuum,' they use the term in a philosophical and *ontological* sense, as the total absence of every type of body.

In this ontological meaning, we must distinguish between a 'relative' and an 'absolute' vacuum. A *relative vacuum* is the total absence of all *ponderable matter*. All elemental substances, whether gases, liquids, or solids, consist of ponderable matter. The subatomic components of elements, namely, electrons, positrons, protons, neutrons, etc., also consist of ponderable matter. They have mass and weight and as such are 'ponderable.' A 'relative' vacuum, therefore, excludes all these bodies and particles of matter, but it does not exclude the presence of 'imponderable'

matter. An *absolute vacuum* is the total absence of all *ponderable* and *imponderable matter*. Aether, for instance, as conceived by physicists, is 'imponderable' matter; so far as they are concerned, it possesses no mass and weight. It is, however, provided it exists, a material, three-dimensional substance. An 'absolute' vacuum, therefore, excludes all physical bodies and the aether.

When cosmologists raise the question of a 'vacuum,' they speak of an *absolute vacuum enclosed* entirely by ponderable or imponderable matter, so that there would be a portion of space within the present universe absolutely devoid of any kind of three-dimensional matter. In this case there would be a space interval between bodies without any connecting substance of any kind, an absolute 'hole' in the universe. We contend that an absolute vacuum, as explained, is *possible*.

There is, to all appearances, *no legitimate reason to deny* such a possibility. The only difficulty physicists encounter in creating a vacuum in a glass tube is of a mechanical character. Given the instrumentalities of necessary efficiency, they see no impossibility in exhausting such a tube completely of all ponderable matter. Supposing, then, that aether is not present, an absolute vacuum would be not only a possibility, but in all probability a fact. If a tube can be exhausted entirely of ponderable matter, there should be no *intrinsic* or *ontological* impossibility in the idea of a tube being exhausted of all matter, whether ponderable or imponderable. The mere fact that one type of matter has mass and weight, while the other has not, is of only secondary importance; as *matter* in three dimensions they

are essentially alike. If there is no contradiction in the notion of a 'relative' vacuum, there is no contradiction in the notion of an 'absolute' vacuum. It is not a question here of the actual possibility of *effecting* an absolute vacuum through physical means, but *of the intrinsic possibility* of an absolute vacuum under any and all conditions.

What man cannot do, because of lack of proper instruments and technique, but which he approaches with a remarkable degree of partial success, must be possible for God's *omnipotence*. If God can remove all matter, ponderable and imponderable, from between the inside walls of a hermetically sealed tube, the tube would actually enclose an absolute vacuum. The partial success of man should become a complete success, when the omnipotence of God is brought into consideration. So long as no contradiction in terms is involved in the concept of an absolute vacuum, it must be conceded to be an ontological possibility. But no such contradiction is apparent. Consequently, it is possible. The possibility of such a vacuum within the confines of the universe receives confirmation from the fact that *space outside the universe* is an absolute vacuum devoid of all matter; if there is no contradiction in the concept of such a vacuum outside the universe, there can be no contradiction in the concept of one *inside* the universe. Hence, an absolute vacuum, completely enclosed by ponderable or imponderable matter, is possible.

The objection is made that an absolute vacuum would *annihilate the distance* between the walls of the enclosing body or bodies and bring them into contact. An absolute vacuum, the objectors argue, is really nothing. But if there

is nothing between one body and another, there is nothing to keep them apart and at a distance; an entity can be measured, but a nonentity can neither be measured nor act as a measure. Hence, under the supposition of a void space interval, two bodies cannot be at a distance from each other, but must necessarily be contiguous. In that case, however, there is no vacuum present between them. An absolute vacuum, therefore, is impossible. In *answer* to this objection we contend that the *distance* between bodies *is not altered* by the intervening vacuum. Let us suppose that we have a hollow steel sphere one foot in diameter, filled with air. God can annihilate or remove the air completely. The walls of the sphere will not collapse, as we know, if the steel of the sphere is strong enough to withstand the atmospheric pressure. The only thing left in the sphere is aether, provided aether really exists. Evidently, God can also annihilate or remove this aether and hinder any other body from occupying the space in the sphere. There is no more reason for the walls to collapse now than there was when the air was removed. Although the inner space of the sphere is a complete and absolute vacuum, the distance between the concave walls remains one foot, because *nothing has happened to the sphere*. The reason is obvious: the space once occupied by an *actual* body is the space for a *possible* body of identical volume, and the distance between the inner walls of the sphere is the same as if the space were filled. It is true, of course, to say that there is nothing between the opposite sides of the inner walls of the sphere; but that does not mean that all space and all distance are eliminated between them, because the space and the

distance of a *possible* body, which God can make *actual*, are there. The objection, therefore, is invalid.

That *relative vacua* are present in the physical universe, can hardly be doubted. The space above the mercury column in the empty end of a thermometer and barometer and the space inside electric-light bulbs and various vacuum tubes must be, if the teaching of physical science on the nature of gases is correct, devoid of ponderable matter either entirely or at least in part. In fact, all the evidence of modern science confirms the theory that the ultimate particles of ponderable matter occupy but a small portion of the space of the universe, because electrons and protons constitute only a small part of the total volume of the atom. Whether *absolute vacua* are present, is a question which science has as yet been unable to answer, because it has no means of direct proof for the presence or absence of aether. That an absolute vacuum is ontologically possible, is clear.

COMPENETRATION AND REPLICATION

Two interesting problems concerning the presence of bodies in place and space are those of the possibility of compenetration and replication. Ordinarily, of course, a body possesses *impenetrability* and *unilocation*: it occupies one place and one portion of space (unilocation) and hinders all other bodies from occupying the same place and space which it occupies (impenetrability). Philosophers have raised the question, whether these natural properties of physical bodies are absolutely essential to them, so that

even God's omnipotence could not remove them, or whether they are merely physical properties, so that a compenetration and replication of bodies would be possible with respect to the omnipotence of God. It would seem that compenetration and replication are *metaphysically possible*.

Compenetration. By this we understand the presence of two or more three-dimensional or *circumscriptive bodies in the same place and space*. Physical or circumscriptive impenetrability of bodies implies two things: first, the actual diffusion in space of the dimensive parts of a body, so that each part occupies a distinct and different part of space; second, the active exclusion from this space of any other dimensive part or body. This exclusion is brought about through a double act: the *resistive power or faculty* of the space-occupying body, and the *resistance* or exercise of this resistive faculty; the former is *aptitudinal*, and the latter *actual*, impenetrability. Compenetration, therefore, would be possible, at least through God's omnipotence, if the actual impenetrability could be removed by removing the 'exercise' of this natural power or faculty, thereby leaving the 'aptitudinal' impenetrability intact.

We must distinguish between various sorts of *penetration*. One thing can penetrate another through 'division,' as when a nail enters a board or a bullet enters a body; also through 'infiltration,' as when a gas or liquid passes into and through the pores of another body; or, finally, through 'compenetration,' as when two or more bodies occupy identical space. We are concerned here only with this last form of penetration, because that alone is

compenetration in the strict sense of the term. A compenetration of this kind is unknown to scientists. Nature presents no instances of it; so far as observation and experiment reach, all bodies possess the most rigid impenetrability. That, however, merely proves that compenetration is a *physical impossibility* and leaves the question of its 'metaphysical' or 'intrinsic' possibility or impossibility unanswered. In order that compenetration be metaphysically impossible, it would be necessary to show that its concept involves a *contradiction in terms*. This, we contend, cannot be demonstrated.

It would be a contradiction in terms to state that a body occupies space and does not occupy space; or, that a body is in this place and not in this place; or, that a body possesses impenetrability and does not possess impenetrability; or, that two or more bodies occupy identical space and do not occupy identical space. None of these contradictory statements, however, are made, when we assume that through the omnipotence of God two or more bodies can be present in the same place and occupy the same space. The only thing necessary would be that God hinder two bodies from *exercising their resistive power* relative to each other. The *exercise* of this power is, after all, only a *secondary act* which follows the primary act of the power itself. Unless, then, the exercise of this power is *intrinsically essential* to a body as a body, compenetration should be intrinsically possible. But it is difficult to understand how or why the exercise of this power should be essential to a body as such, since bodily extension demands merely side-by-sideness or extraposition of its parts relative to one another and to the

whole. Hence, it would seem that *no contradiction in terms* is involved in the concept of compenetration. We are, then, philosophically justified in assuming that the compenetration of bodies is intrinsically and metaphysically possible.

Replication. By replication is meant the *simultaneous* presence of one body *in more than one place*, of which each place would suffice of itself to contain the entire body. If it is a question of two places for the same body, it is a case of *bilocation*; if of more than two places, *multilocation*. Experience and observation show that a body is either stationary in one place or moves from one place to another, but it has never been observed that a body can be simultaneously in two or more places. By means of induction, then, it is certain that replication is *physically impossible*. However, as in the case of compenetration, this would not necessarily establish the fact that replication is intrinsically and metaphysically impossible. That point can still be argued, taking the omnipotence of God into consideration. Certainly, if replication involves a contradiction, it is intrinsically and metaphysically impossible. If, for example, a *duplication of place* would necessarily bring about a *duplication of the body*, that would be a contradiction in terms. The supposition is, that *one* body can be in two separate places, and the actual result would be that we have, not one, but two bodies, each of which occupies its own place; one body would be two bodies, and that is a contradiction in terms. The real difficulty of the problem consists precisely in this: Can a

body retain its *unity of being* in such a supposed bi-location or multi-location? It would seem that it can.

The unity of a being depends entirely on the *unity of substance*; so long as the substance or entity is one, its being is one. But the unity of substance does *not* depend on the unity of *place*. This is obvious from the fact that bodies change places without changing their substance or entity. Hence, the multiplicity of place does not, in itself, necessarily induce a multiplicity of substance. Of course, from the fact that bodies can occupy different places successively, it does not follow that they can do so simultaneously. Whether, however, the time element, though naturally important, is *essential* to the problem, is questionable. Since 'presence in a place' is something totally different from 'unity of substance and being,' the successive or simultaneous 'presence in a place' should not affect the substance as such. To assert that a simultaneous presence in two places automatically induces a duplication of the body's substance, is simply to beg the question at issue. If there is no contradiction in terms in assuming the presence of two bodies in one place (compenetration), there can hardly be a contradiction in assuming that one body can be in two places (replication). Compenetration does not fuse the substance of the two bodies into one, and replication should not increase the substance of one body into two. To say that a body is in two places and still only in one, or that it is in one place and yet in two, would indeed be a contradiction; but that is not the case here, because the 'presence,' not the 'substance,' of the body is said to be duplicated or multiplied. A contradiction in terms,

therefore, is not evident. Hence, although the argument is indirect, the opinion, which holds that replication is intrinsically possible, is probable.

Modern scientists, especially those who follow Einstein's theory of relativity, speak of 'non-euclidean' space, 'curved' space, space-time,' and so forth, when referring to the space of the universe. This will be discussed later. Our present interest lies in the philosophical analysis of the concept of place and space; as such, they are not actual realities, but conceptual entities, based on the physical extension of material bodies.

SUMMARY OF CHAPTER VII

Closely related to quantity and extension are the concepts of place and space.

1. *Common Meaning of Place and Space.* According to the common usage given to these terms, 'place' and 'space' are three-dimensional, stationary, and immobile containers or receptacles of bodies, and as such are considered to be distinct from the bodies contained.

2. *Philosophic Concept of Place.* The internal place of a body is the outside surface of this body, considered as the receptacle of the body's entire volume. The *external* place of a body is the surface of the object or objects immediately enveloping this body; this is the *proper* place of a body. The *common external* place is the general position of a body with respect to other bodies at some distance from it.

3. *Ubication.* It is the presence of a body in a definite place. *Circumscriptive* presence is the presence of a body in such a manner that it has parts outside parts in the place where it is. *Definitive* presence is the presence of a spatially unextended substance in such a manner that it can exercise its activity only within certain limits of space. *Repletive* presence is the presence of a spatially unextended substance in all space, past, present, and future.

4. *Philosophic Concept of Space.* Different views have been held by philosophers: space is an actual reality; the immensity or infinity of God; the absolute; a purely subjective sense form; the stuff of the world; relations between bodies; extended substance; concrete extension of

existing bodies. Scholastics distinguish between real, possible (ideal), and absolute space, and maintain that *space is a conceptual being with a foundation in physical nature*.

5. *Space Not a Real Being*. It cannot, as conceived, be an infinite and eternal reality, because that would involve infinite magnitude and number. It would be a three-dimensional material substance, a body; since, however, a body is contained in space, this space would demand another space, and so forth in infinite regress. It is not God's infinity or immensity, because these attributes are one with His spiritual essence; space, however, is not spiritual, because it is extended. It is not the external relations of bodies, because space extends beyond the universe where there are no bodies. It is not extended material substance, or extension itself, because space may be filled or empty and is conceived as the receptacle of extended substance and extension.

6. *Space Not a Purely Mental Being*. Our experience shows that our concept of space comes from external bodies. *Science* proves that extended bodies are real. Such bodies, however, exist in space. Hence, space is related to bodies in nature as their receptacle. Consequently, there must be a foundation in nature for our concept of space, and so this concept is not purely mental.

7. *The True Nature of Space*. We acquire our concept of space through abstraction from the concrete extension of bodies in nature. Hence, space is *abstract extension considered as a receptacle for bodies*; as such it is a conceptual being with a foundation in real things.

8. *Vacua*. A vacuum is the *total absence* of a material, three-dimensional substance in the universe. A 'relative' vacuum is the absence of ponderable matter; an 'absolute' vacuum is the total absence of all ponderable and imponderable matter. An *enclosed absolute vacuum*, one surrounded completely by ponderable or imponderable matter, is possible. God could completely exhaust a steel sphere of all matter.

9. *Compenetration and Replication*. Corn penetration is the presence of two or more circumscriptive bodies in the same place and space. It cannot be said to involve a contradiction; hence, it is intrinsically possible. All that is necessary is that God hinder a body from exercising its resistive power. Replication is the simultaneous presence of one body in more than one place (bilocation, multilocation). This also seems to be intrinsically possible to God. The unity of a being depends on the unity of its substance; and the latter does not depend on the unity of place, since bodies change places without change of substance. It cannot be shown conclusively that the 'simultaneity of place' or the 'duplication of place' would necessarily induce a 'duplication of substance.'

Chapter 8

QUALITY AND ACTIVITY

WHILE QUANTITY AND EXTENSION ARE OBVIOUS PROPERTIES of bodies and can be subjected to very accurate measurements, there are other properties which are equally important, though they cannot be described in meters and grams. These are the *qualities* and *activities* of bodies. Most scientists are no longer content with the description of the quantitative features manifested by bodies; they have come to the realization that the qualitative properties are even more distinctive and informative. This is due mainly to the study of energy and the activities of bodies resulting from energy.

Since the *inner nature* of bodies cannot be observed directly, but only *indirectly* through its properties, it will be necessary to examine those qualities and activities which are more generally found in all bodies, because it is the purpose of the cosmologist to determine, if possible, the nature of bodies in general.

THE CONCEPT OF QUALITY

The term 'quality' is used in many meanings. Almost any modification and determination of things is designated as a 'quality.' In a strict sense, *Aristotle* describes it as follows: "By 'quality' I mean that in virtue of which people [and things] are said to be such and such."¹ This description is rather vague. A more definite wording can be given to convey the meaning of 'quality': *A quality is an absolute accident completing and determining a substance in its being and in its operations.*²

For a better understanding of quality, it will be necessary to have a clear conception of 'substance' and 'accident.' A substance is a being whose nature it is to exist in itself and for itself, needing no other subject in which to inhere in order to exist. A substance has an amount of entity of its own sufficient for independent existence. Such are electrons and protons, elements and all compounds, plants, animals, and men. An *accident* is a being whose nature it is to inhere in a subject in order to exist. An accident, therefore, is too weak in its own entity to exist in itself and for itself; it needs a subject, a substance, as the support and bearer of its existence. An accident is always the modification and determination of an existing substance. Such are extension, heat, magnetism, electric charge, motion, crystallization, color, resistance, cohesion, activity, shape, etc.; they always presuppose a substance as the subject which they modify and in which they exist.

Some accidents are relative, others absolute. Accidents are *relative*, when their being consists merely in the bearing which one thing has to another. That things are equal in size or number, similar in color or structure,

inferior or superior in value, etc., is due to their mutual bearing toward each other. Accidents are *absolute*, when they confer a real perfection of some kind on the subject in which they inhere. Quantitative dimensions are such; and so, too, are qualities, as will be seen from the definition of quality given a moment ago.

A quality completes and determines (modifies) a substance in its being and in its *operations*. There are, then, two main kinds of qualities: *entitative*, which modify the substance in so far as it is a being in itself, and *operative*, which modify the substance in so far as it is capable of activity and change. The former are more static and passive in character, the latter more dynamic and active. It would be erroneous, however, to draw too sharp a line between these two types of qualities. While the entitative qualities are characterized more by the tendency to stabilize the substance in its own being, there is a certain amount of activity which accompanies the exercise of these qualities. And while the operative qualities manifest themselves more in action, especially in influencing and changing other substances, they also tend to bring about an entitative stabilization of the operating substance itself. This division of qualities is, therefore, more a matter of convenience than of exclusiveness, and this should be borne in mind during the following discussion.

ENTITATIVE QUALITIES

What has just been said concerning the division of qualities into two main kinds, applies also to the following division of

entitative qualities: it is *not exclusive*. Many of these qualities affect matter as such and will, therefore, be present in all states of bodies; other qualities overlap various states. Since it is impossible to mention all qualities found in the manifold types of substances, a selection is made of those entitative qualities which seem to be most *general* and *fundamental* in all types of bodies.

Subatomic States. Subatomic particles, such as electrons, positrons, protons, neutrons, photons, cosmic rays, etc., possess certain states which are decidedly qualitative in character and cannot be explained on the mere basis of quantity. It is necessary to postulate 'qualities' as the root-principles of their existence and nature. That these particles are three-dimensional, is a consequence of their quantity. These particles, however, are qualitatively distinguished in so far as the *amount* and *weight* of their matter (ontological mass) is definitely fixed and stable. We know, for example, that the mass of a proton is about 1845 times that of an electron or positron. Perhaps the most remarkable qualitative difference in these subatomic particles is that of their *opposite electric charge*, which has a fixed and unchangeable character; it affects not only the particle themselves, but also the surrounding medium, producing therein a *field of force*. It is also very probable that they are magnetic in their very constitution. *Inertia* may be a quality, because inertia is, it would seem, something more than the sheer passivity of matter; its ultimate nature is not well understood.

Atomic States. There are a number of qualitative states in the atoms which attract our attention. The nuclear atom

(if the nuclear theory is correct) has a precise *structure*, due to the disposition and configuration of its electrons, protons, and neutrons. This structure is not fortuitous; it is carried out according to a progressive *plan*, as can be seen in the Table of Elements. The differences of properties in each series and the periodic recurrence of similar properties in each group, is evidence of the functioning of entitative qualities of a high order. Furthermore, the aggregation of positive protons into a *nucleus* (although they have the natural tendency to repel each other), attracting some electrons closely and keeping others at a distance (as is evidenced by ionization), can only be explained through the mysterious working of deep-seated qualities which are capable of overcoming the powerful tendencies of their charges. Another qualitative characteristic of the elemental atoms is the *metallic, basic, electropositive* property of those at the beginning of a series and the nonmetallic, acidic, electronegative property of those toward the end of a series, together with the tendency to unite and *neutralize* each other. Throughout these series of elements we observe the fundamental feature of the *octet formation* of planetary electrons, which is most noticeably perfected in the Zero elements, resulting in a balanced, symmetrical, *equalized system*. This accounts for *valence* and partly for *affinity*. Although the various elemental atoms (with the exception of the Zero elements) can give or take valence electrons to form a compound, each resists to the utmost any change or modification of its essential structure: *preservation of identity* is a cardinal property of all atoms. The radioactive elements appear to

be an exception to the law; but even in their case, the emission of alpha and beta particles proceeds according to an intrinsic constitutional necessity in such a manner, that there can be no doubt that unknown qualitative agencies are at work in accordance with a law of their own, since the entire process of disintegration follows an exact sequence and ceases with the production of radio-lead. Another entitative state of each type of atom, due to the agency of an internal quality, is the *fixed volume* which each atom tends to assume and maintain.

Molecular States. There are entitative states peculiar to molecules. Some molecular states of *aggregation* are characteristic. There are elemental atoms which, in their free condition, never unite with another atom of the same element, so that they are monatomic; such is, for example, helium. Others, like oxygen and nitrogen, combine in twos; they are diatomic. Others are triatomic, etc. We say that *cohesion* is responsible for the union of two or more atoms in such a combination; but that is merely a term designating an unknown quality, similar to the term *adhesion* designating another type of molecular attraction. Cohesion and adhesion account for the fact that bodies do not break up into atoms, but appear in closely knit masses. All bodies can assume *gaseous, liquid, and solid states*, depending mainly upon pressure and temperature. Related to these three states are the *fusion* point and the *boiling* point of bodies; under identical conditions these points are determined and fixed. A molecular state, remarkable both for mathematical precision and beauty of structure, is the *crystalline form* of many, and most probably all, substances

of an inorganic nature. What kind of atomic and molecular forces are at work in the development of crystals, scientists do not know. It is certain, however, that we are face to face here with an entitative state of such a pronounced qualitative character, that the ordinary forces present in atoms and molecules will not suffice to give an adequate explanation of the phenomenon.

Molar States. By 'molar' states we understand the states pertaining to larger masses of matter, as distinguished from the masses of atoms and molecules as such. All bodies have the property of *compressibility* and *expansibility*. Under standard conditions, for instance at 0°C and 760 millimeters pressure of mercury, each substance has a definite *density*, so that a certain number of units of mass will occupy a unit volume of space; thus the density of air is 1.293 grams per liter. With the application of heat, or the reduction of pressure, or both, a body will yield to its internal expansive force and occupy a greater volume of space. With the application of pressure, or the reduction of heat, or both, the internal expansive force is partly overcome, and the body will occupy a smaller volume of space. Liquids in small quantities tend to assume a globular shape, as can be observed in a drop of water or mercury, and even large masses of bodies, such as the stars, show the same tendency; this shape is effected by the force of mutual attraction, when bodies are free to move in response to the force. All, of course, have the universal property of *impenetrability*, because it is a fundamental property of matter in all its states. Inasmuch as magnetism is a concomitant phenomenon of electricity, and since all

matter is electrically charged, it follows that *magnetism* is, to a greater or less degree, found in all material substances; often, however, it is present in a neutralized condition and therefore unobservable. Some substances are *paramagnetic*, because they have the property to condense magnetic lines of force; others are *diamagnetic*, because they tend to disperse these lines. Other properties and states, frequently found in bodies, are *hardness, softness, smoothness, roughness, elasticity, tensile strength*, etc.; they are the result of molecular arrangement. There are also varying molar states due to the *conductivity* of heat, electricity, and similar agencies.

These various states and conditions are predominantly 'entitative' in character, because they affect the *being* of substances. They can only be accounted for by the presence of special and general *forces* whose function it is to produce these states, and all such forces go under the general name of 'entitative qualities.'

OPERATIVE QUALITIES

'Operative' means to be 'capable of action.' To 'act' means to do something, to produce some effect, to perform work, to cause a change to occur; or, reversely, it means to receive an effect, to react to an agency, to experience a change in response to some influence exerted upon it. 'Operation' or 'activity,' then, is the exercise of a power or faculty capable of action. Such powers or faculties are *operative qualities*.

All bodily substances without exception manifest activity of some sort. The universe is a tremendous theater of unceasing activity. The most obvious example is local motion. The movement of the stars, the rush of the wind in a storm, the pounding of the surf on the shore, the falling of the rain, the flight of a bird, the speed of a racing automobile, the walk of a man — all are instances of activity in nature.

The concept of ‘operation’ or ‘activity’ is inseparable from the concepts of ‘change,’ ‘cause,’ and ‘effect.’ Whenever there is an activity present, a *change* occurs and something new happens. This change takes place either in the ‘agent’ or in the recipient of the action; the reception of the action on the part of the recipient is called ‘reaction,’ and the recipient is called the ‘reagent.’ Action and reaction occur together, and every action presupposes an active potentiality in the agent and a passive potentiality in the reagent. By means of its action the agent actualizes the passive potentiality of the reagent, and therein consists the ‘change.’ In every change something is produced. That which is produced, is the *effect*; that which is actively engaged in bringing about this production, is the *cause*; and the action of the cause in the production of the effect is *causation*.³

An *operative quality* or, as it is also termed, *natural capacity* is defined as a *proximate accidental principle of operation, toward which (operation) it is specifically directed*. It is said to be the ‘principle of operation,’ because the operation proceeds from it. It is the ‘proximate’ principle, in order to distinguish it from the remote

adequate principle of operation, namely, the being's nature or substance; the nature or substance acts through, and by means of, the faculty or operative quality. It is the 'accidental' principle of operation, because it is a power and faculty; we thus distinguish it from any integral or substantial part of the being which may also be a principle of operation, as, for example, the hand or a muscle. Finally, it must be 'specifically directed' toward a certain operation, in order that it may be said to be the faculty or operative quality of this particular action; the intellect, for instance, is the faculty of thinking, because thinking is the special kind of action which proceeds from it and toward which, therefore, it is 'specifically directed.'

It would be useless to attempt to enumerate all the operative qualities found in nature; they are as numerous as there are different kinds of activities. The cosmologist is interested only in the more *fundamental classifications*. And since we recognize faculties or operative qualities only through and in their activities, the best procedure will be to outline the main types of activities. The two main types are 'transient' and 'immanent' activity.

By *transient* (transeunt, transitive) activity we mean the activity which *tends to change another object*, distinct from the agent, thereby making this object the term or goal of the acquired actuality. The agent and recipient are two distinct beings; the agent influences and modifies the recipient, while the recipient is thereby influenced and modified. By *immanent* (vital) activity we understand the activity by means of which a living being perfects itself and *makes itself the goal* for the acquired actuality. Such an

activity does not tend to leave the agent, in order to actualize or change a being distinct from itself; rather, it begins and terminates in the agent itself, so that it is also the passive recipient of the perfection acquired through its activity.

TRANSIENT ACTIVITIES

Transient activities are peculiar to inorganic *substances*. We can group these activities into three broad classes: chemical, physical, and mechanical.

Chemical Activities. Atoms, molecules, and compounds act and react among themselves, thereby effecting various combinations and decompositions. The entire science of chemistry is devoted to the study and explanation of these activities, their processes and results. All material substances have a double aspect; they are both *active* and *passive*. In so far as they have operative forces of their own, they are active and tend to change others by communicating their own properties to them; and in so far as they lack certain actualities, they are passive and subject to outside influences, so that they are changed by them. This is the basis for all transient activities and changes of a chemical nature.

Chemical forces are very powerful, and the changes effected by them are very profound. This is proven by the relatively great amount of heat which is absorbed or emitted in *endothermic* and *exothermic* reactions. That electricity also plays a prominent part in chemical changes, can be seen in *electrolytic* processes. Particularly

noticeable is the *affinity* or selective tendency of combination which exists between the metallic and nonmetallic elements. While it is true that the tendency to form an octet of planetary electrons in the outer shell of an atom plays a prominent part in the selection of certain elements for mutual combination, this does not seem to be an adequate explanation of affinity. It is a common phenomenon in chemical reaction that one element will force another out of a compound and replace it, although the octet formation is established by both. This seems to demand operative forces of a special kind, distinct from those whose tendency it is to complete the octet.

When elements and compounds come in contact with each other, each influences the other. This brings about a mutual *toning down* of these properties, with a resultant *neutralization and equalization* between them, which eventually establishes a most intimate *union* between the various elements participating in the reaction. As the final outcome of chemical reaction we observe a compound with a stable character and a *new behavior*. Chemists say that such changes bring about a *new substance*. This is meant, of course, in a chemical sense; whether these changes are 'substantial changes' in a philosophical sense, is a matter which shall be discussed later. That the properties and activities of the new substances are radically different from those of the component elements, is a fact of common observation. One need but compare those of water with those of oxygen and hydrogen, or those of ordinary salt with those of sodium and chlorine, in order to note the great change which has taken place in the reaction. Inorganic

substances are identified by their various physical and chemical properties. Among the *physical properties* are color, odor, taste, solubility, physical state, and density; among the *chemical properties*, stability toward heat, light, and shock, and behavior toward other substances at different temperatures. All these undergo modification in chemical change.

Physical Activities. While chemical activities tend to change the chemical substances, physical activities tend to change the *qualitative states* of these substances. This is done through energy. The energies at work in physical change are *sound, light, heat, electricity, and magnetism*. The entire field of radiation belongs in this class. Everyone is familiar with the manifestations of these forms of energy and the changes effected by them. We owe the conveniences of our modern civilization to the application of these energies to our need and comfort. Telephone and telegraph, steamship and train, automobile and airplane, radio and television, electric light and household appliances — all are inventions based on the intelligent use of these physical forces. All substances in nature, from electrons to stars, are subject uninterruptedly to the *interplay* and *transformation* of energy, and most of the observable phenomena present in the universe are reducible to the intense activities of these agencies.

Mechanical Activities. Mechanical forces tend to produce *motion* and effect a *change of position* among material substances. All activities of the various forms of energy are accompanied to some extent by mechanical motion and all tend to produce it. There is subatomic

motion in the electrons and protons, whether bound together in atoms or in the free state. Electromagnetism attracts or repels them. Atoms and molecules are in a continuous state of agitation, as can be seen in the Brownian movements. Solids liquefy, liquids flow and vaporize to gases, and gases are in constant commotion. Chemical combinations and decompositions involve spatial movement; explosions are an extreme instance of the fact.

Distinct from the physical and chemical agencies just mentioned is *mechanical impulse*; it is the shock of a moving body producing motion in another. This includes all types of collision, from the bombardment of atoms by subatomic particles to the cosmic hurtling of a comet or meteor against a star. The most potent of all mechanical forces in the universe is the force underlying the phenomenon of gravitation. It affects every particle of ponderable matter, drawing them toward one another with irresistible bonds. It is one of the factors responsible for the movements of the heavenly bodies, namely, the centripetal force which attracts all planets toward the sun.

Physicists often state that a body in motion, on impact, 'communicates its motion to another.' This is either a metaphorical expression or it is an erroneous conception. Motion is not something which can leap from one body to another. Motion is a *body moving* from place to place; it is a *state* of being, *not an entity* distinct from the moving body itself. Hence, motion cannot leave one body and pass over to another. What happens is this: On impact, the striking body activates the mechanical force of motion present in the body suffering the impact and, since action and reaction

are equal, it loses as much activity as the other acquires; a *new motion* arises in the second body, while the original motion in the first body decreases correspondingly or even ceases altogether, depending on the weight of the two bodies and the angle of collision.

Such are the main types and features of transient activities. Of an entirely different kind are immanent activities.

IMMANENT ACTIVITIES

Immanent activities are peculiar to *living beings*, whether of a material or spiritual nature. Since, however, the cosmologist is concerned only with bodily beings as existing in the physical universe, and since living bodily beings are organisms, immanent activity, in this connection, is identical with *organic activity*. Strictly speaking, organic activity or vital function is the subject matter of psychology and will receive full treatment in that department of philosophy. Nevertheless, organisms are *real bodies* and integral parts of the universe. Therefore, they cannot be ignored by the cosmologist. Nor can their activities be passed over in complete silence, because organisms are composed of the material elements and utilize their activities in vital functions. The contrast between inorganic and organic activities throws an interesting side light on both. A short description of the immanent activity of organisms will, therefore, not be amiss.

There are, so far as we know, only three types of organic beings in our universe: *plants, animals, and men*.

Plants: Vegetative Function. The organic substance which is the seat of life is the protoplasm, and the unit of organic structure which carries out vital function is the *cell*. Protoplasm, though it consists ultimately of the ordinary chemical elements, represents a synthesis of extreme diversity and complexity, and nothing even remotely resembling it is found anywhere in inorganic compounds. Left to themselves and operating under the force of their own innate powers, the elements are incapable of forming *organic compounds*. The only inorganic structure which will bear comparison with the cell is the crystal; but the crystal is rigid, dead, devoid of activity, and without any trace of internal *organs* possessing the *differentiation of function* so manifest in the living cell.

Plants, the lowest form of organic beings, have a number of distinctive immanent activities. The most fundamental of these is *metabolism*, the process through which the cell draws into its structure extraneous matter and energy necessary for its vital function. Metabolism comprises a double cycle, the 'anabolic' and 'katabolic.' The former takes the elements with their energy contents, synthesizes them into special compounds, and makes them part of the cell's structure; the latter breaks down these compounds through oxidation, thereby liberating the stored energy for use by the cell.

Next, we see *growth and development*. Through intussusception the process of nutrition builds up the body of the organism to normal size. All plants have a definite structure which is typical of the various species to which they belong. Some consist of a single cell, such as the

amoeba, others develop into gigantic trees with billions of cells, such as the redwoods; some are terrestrial plants, others marine plants; some are vines, others are bushes or trees; some have flowers, others lack them; and so on, through a million specific forms and shapes. Each tends to realize its own *type* through nutrition and specialization.

The power and activity of *reproduction* is one of the most remarkable phenomena of nature. Not only does the plant tend to preserve its own identity as an individual, but also the identity of the species of which it is an individual. The methods of reproduction vary; it may be through direct *fission*, or *mitosis*, or *budding*, or *sporulation*, with or without special sex organs.

Another activity is the plant's adaptation to external stimuli. It seeks to preserve its identity at all cost, changing structure and function to meet the influence of its environment, repairing damaged parts, even regenerating entire structures which have been lost. This power of regeneration is less noticeable in the higher and more specialized forms of life, but the power of adaptation in its general features is found in all plants, animals, and men. Another universal property of living tissue is *irritability*, i.e., the reaction to stimuli; this reaction is of such a character that it results in the well-being of the organism as a whole.

Animals: Sensory Function. In common with plants, animals have the vegetative functions just enumerated, modified and specialized according to the demands of their own peculiar kind of life. Besides these functions, however, animals have a type of function distinctively their own, *sensation* and *perception*, which is a vital function

beginning with the stimulation of a sense organ by an appropriate object and ending in the perception of the stimulating object. There are different kinds of sensation, depending on the different kinds of sense organs. Not all animals are endowed with every kind.

All animals apparently possess the faculty of what is commonly called 'touch' or 'feeling,' but which is more accurately termed the *somesthetic sense*. It is concerned with the experience of bodily conditions and processes. There are sensations of pressure, pain, and heat; sensations of movement in the joints, muscles, and tendons; sensations of equilibrium; sensations of organic needs, satisfactions, fatigues, illnesses, and general well-being.

Taste and *smell* are found in many, but not in all animals. They are chemical senses, stimulated by the chemical properties of bodies. The two senses are closely associated in their operations, and the perceptions arising from each are often confused. The qualities perceived by means of the sense of taste are primarily four: bitter, sweet, saline, and sour savors. Psychologists are at variance in their enumeration of the primary qualities which affect the sense of smell. The following division answers the purpose: flowery, fruity, spicy, resinous, putrid, and burned odors.

The sense of *hearing* responds to the undulatory movements of different media and depends on the frequency and amplitude of the waves impinging on the organ. The range of the vibrations which are audible varies, of course, with different classes of animals. In the case of man the range extends between about 20 to 20,000 frequencies per second. The organ of *sight* or *vision* reacts

to light and to the shape and color of objects. Elements and compounds have the selective power to absorb certain light frequencies and reject others. The latter are reflected from the objects, enter the eye, and affect the rods and cones of the retina; the retina is the physiological seat of vision. The nerves and the brain participate integrally in every process of perception.

These senses are located primarily, though not exclusively, in *peripheral organs*, i.e., in organs which are situated in or near the surface regions of the body. A few senses are located primarily in the brain and are termed *internal senses*; they are the common or central sense, imagination, memory, and instinct or estimative power.

The *common* or *central sense* makes animals aware of their sense acts. This sense consciousness notifies them of the presence of the perceptive acts just mentioned, and also of emotional states, such as pleasure, pain, anger, desire, and of appetitive striving. It enables them to distinguish in a concrete way between the various organs and perceptions and to locate them in the bodily system. This is fundamentally a coordinative sense.

The *imagination* is the power of re-presenting concretely objects which have previously been perceived but are no longer actually present in perception. To a very great extent it is associated with sense memory, which is the power to recall objects and events of the past and to locate past experiences in their proper sequence of time and place. Imagination, however, must not be identified with memory. The imagination can use the materials supplied by the sense perceptions to form images of its own fashioning,

without any regard to conditions of time or place as having been experienced in the past; dreams and the play of fancy belong to this class of imaginative activities.

Estimative power is the ability to recognize in a concrete manner objects which are good or bad for the organism of the animal. As a result of such knowledge, animals may and usually do, perform certain very purposive acts or complicated sequences of acts, although they have no knowledge of the purposiveness of such acts through experience. The urge to perform these acts exists in them prior to all experience. The modern term *instinct*, in addition to the estimative power which is the cognitional element, includes also emotional and motor elements. The influence of instinct is noticed chiefly in actions which are necessary for the preservation of the individual and of the race.

The cycle of perceptive acts is completed in the animal in its *emotional states*. They are the manifestation of *appetitive* powers, by means of which the animal desires an object and strives to obtain it as a good. Feelings and emotions play a dominant part in the life of all conscious organisms as concomitant phases of appetitions. Following the knowledge of an object, an impulse arises in an animal to seek what is pleasant and fend off what is unpleasant; this brings about definite changes in the organic mechanisms of the individual, especially in those which are glandular. This complex set of activities is comprised under the general term *orexis*.

Since the mere desire of an object will not enable the animal to obtain it, it is endowed with the power of

locomotion. Unlike the plants, especially those of a higher order, which are fixed in the soil, animals can move about more or less freely. They have muscles which are activated by motor nerves. Some muscles are 'voluntary,' others are 'involuntary'; these terms, however, are rather inappropriate, because they apply, strictly speaking, only to man and his rational will. What is meant is that some muscular actions are subject to conscious control, while others are not. Types of locomotion are: the swimming of fishes, the crawling of reptiles, the flying of birds, the walking and running of bipeds, quadrupeds, and many-footed animals.

Men: Rational Functions. So far as we know, man represents the highest form of life among the organic beings in the universe. He possesses the vegetative functions of the plant and the sensory functions of the animals. He also possesses vital functions which are specifically his own, namely 'intellection' and 'volition.'

Intellection appears in three phases: ideas, judgments, and inferences. *Ideas* are the intellectual representations of things, and they are very different from the sensory representations of things. Sense images are concrete and individualized; ideas are abstract and universalized. Sense images represent single objects; ideas represent types and classes. Sense images reveal the traits in which single things differ and are particularized; ideas manifest the features which things have in common and which enable the intellect to group them into general classes. *Judgments* are acts of the intellect affirming or denying one idea of another, showing their mutual agreement or disagreement.

And since ideas are representations of things, judgments express the relationships which the intellect conceives to exist between these things in the order of reality. If the judgment agrees with these objective relationships, it is true; if not, it is false. Judgments, therefore, contain truth and error. *Inferences* are a mental process, by which, from certain truths already known, the intellect passes to another truth distinct from these but necessarily following from them. In 'induction' the intellect concludes from particular instances to the existence of a general truth or law; in 'deduction' it concludes from the general truth or law to the truth of a particular instance. The reasoning which underlies all research in science and philosophy is reducible to these two fundamental types of inference. Man also has the faculty of *understanding*, which consists in a direct, intuitive knowledge of principles and things. *Language* is the expression of intellection: that is the reason why man alone is gifted with language.

Volition or *rational appetite* is the activity of the will inclining toward, or striving after, some object intellectually apprehended as good. Man has *free will*, namely, the capability of choice or self-determination. His will necessarily strives for the good; but between motives and alternatives it has a free choice of selection, and the decision lies entirely within the power of the will itself. Though man can choose as he desires, his will is bound by the obligations of the *moral law*. Decisions in conformity with the moral law are morally good; those not in conformity with it are morally evil (sinful, wicked, criminal). Good actions are deserving of merit and reward; evil

actions, of condemnation and punishment. *Conscience* approves of actions conforming to the moral law and condemns those in opposition to it. Our entire concept of society, government, human rights and duties, and judiciary processes has its basis in the fact that man's volition is free in its choice between good and evil.

Concomitant with all these rational functions is *intellectual self-consciousness*. Man, unlike the brute, is conscious of self, of his own *Ego*, in the acts of thinking, willing, and sense perceiving, and he recognizes his own self as the subject of these acts, as the agent who performs them and in whom they occur. He is also aware that these acts and states differ among themselves, while he, in whom they take place and in whom they inhere as in their subject, is one and indivisible, an unchanging, permanent reality amid all the changes which occur within his person. Man alone, among the various kinds of beings existing in the physical universe, is a *person*, i.e., an individual, complete, intellectual substance which is self-contained and autonomous in its operations.

Even this extremely brief outline suffices to bring out with striking clarity the sharp line of demarcation which divides the *immanent* activities of living beings from the *transient* activities of inorganic substances. They are *specifically* different and must have their respective origins in specifically different principles. Hence, the ultimate essential constitution of organic and inorganic bodies must also be of a specifically different nature.

This concludes our investigation of the various general kinds of 'entitative' and 'operative' qualities. There is no

further need to prove that *qualities actually exist* in nature. Our enumeration is not mere speculation. These activities and tendencies of bodies are facts which are verified by everyday experience and by exact scientific observation and experimentation. The principles, however, from which these activities and tendencies proceed, are termed 'qualities.' Consequently, qualities exist. The scientist speaks of 'energies' and 'forces,' while the philosopher calls them 'qualities.' The thing is the same; and it is the thing, not the name, that counts.

ACTION AT A DISTANCE

One of the interesting problems which has emerged from the philosophic examination of bodily activities is the question of the possibility or impossibility of '*action at a distance*.' The term, however, must be properly understood.

Ordinarily, agent and reagent must be present to each other in some manner, in order that the causal action of the former can produce an effect in the latter. This presence may be either 'immediate' or 'mediate.' One thing may be *immediately present* to another in a variety of ways. For example, through the substance itself, as when the mind of man produces a thought of the intellect or an act of the will. Or, by means of a substantial union, as when the soul of man performs vegetative and sensitive functions or locomotion in its own body. Again, by means of contact, as when a man drives a car, wrestles with another, throws a ball, pushes a cart. In these cases no other being intervenes between the cause which acts and the recipient which is

influenced by the causal action. Not all instances of action and reaction are of this kind. In many cases some other body or bodies intervene between the agent and reagent, so that the agent and reagent are only mediately present to each other; the action of the agent reaches the reagent through the mediation of the intervening body or bodies. The manner of being *mediately present* to another differs, depending on the various kinds of mediation possible. Thus, it may be a case of using an instrument, as when a carpenter uses a saw, a welder uses a blowtorch, a butcher uses a knife. Or, it may be by means of some sort of emanation, as when a flower affects the sense of smell through chemical effluvia and the sun influences the eye through light waves. Again, it may be by means of an action impressed upon another cause which is in immediate contact with the reagent, as when a cue ball strikes the first ball of a series of billiard balls set in a row, so that the last one of the series is impelled in a forward direction. In all such instances of mediate causal action, the reagent is at a distance from the agent, and this is, in a true sense, 'action at a distance.'

That, however, is not the sense of the term 'action at a distance' in the meaning of the problem here under consideration. The problem is concerned with the action of an agent upon a reagent *across an absolute vacuum*, so that the agent and the reagent are 'at a distance' from each other *without immediate or mediate presence* in any manner whatsoever. Not even imponderable matter, such as aether, would be present, so as to bridge the absolute gap between them and carry the causal action from the one to

the other; the space interval between them must be devoid of every sort of medium. It is in this restricted meaning that the question of the possibility of an 'action at a distance' becomes a real problem.

Dynamists, who reduce the extension of bodies to indivisible points separated by empty space intervals, maintain that these points act upon one another through forces which fill the intervening empty space. This amounts to an action at a distance. *Kant*⁴ and *Lotze*⁵ also defend the view that forces can act at a distance. Those adherents of the modern theory of *relativity* who deny the existence of the aether in interstellar space, must also, if they are consistent, advocate action at a distance. *Physicists*, generally speaking, deny the possibility of action at a distance. *Scholastic* philosophers, as a rule, maintain its impossibility, although some, among them *Mercier*,⁶ contend that it is possible and consider the arguments adduced to prove the metaphysical impossibility of such action to be unconvincing and invalid.

The problem can be approached from two angles, the physical and the metaphysical. From the standpoint of the former, the question arises whether 'action at a distance' is a *physical possibility*, i.e., whether, according to the laws operating in nature, it is possible for one body to causally influence another separated from it without any intervening medium. From the standpoint of the latter, it is the question whether such an action is a *metaphysical possibility*, i.e., whether it is intrinsically possible in itself, due to the fact that there is no contradiction in terms involved in the very idea of an 'action at a distance'; if it involves a

contradiction, it is metaphysically impossible, and then even God's omnipotence cannot make it possible. Whatever is physically possible, is also metaphysically possible; reversely, whatever is metaphysically impossible, because contradictory, is also physically impossible.

It seems that it can be established that an '*action at a distance*' is *metaphysically impossible*. Let us quote from Cardinal Mercier; he defends the possibility. "The *force* put into play we cannot conceive to be anywhere but in the agent; for if it is an accidental property it depends upon its subject of inherence, and if a substance, it is identical with the agent. The *effect* is wholly in the recipient subject which occupies a position outside the agent. Now, does action pass from the agent to the patient? Certainly not; the agent does not cause any accidental reality originally belonging to itself to pass over into the recipient subject, otherwise every efficient activity would be reducible to a simple displacement of pre-existing realities, to a passing over of accidents. Therefore no transference takes place, nothing passes from one to the other; the effect is a new birth, and takes place entirely within the patient under the influence of an external cause (*Gen. Metaphysics*, no. 144)." He concludes by saying: "In this analysis neither contact nor distance appears as an indispensable condition of activity."⁷ On the contrary, to us it would rather appear that his analysis proves that *contact* (mediate or immediate) is a requisite condition of transient activity, when one body influences another; a complete vacuum would make such an influence impossible.

It is true, as Mercier states, that a *force* is an *accident* and must inhere in its substance as in its subject; it does not pass from the agent to the recipient. The action of the agent can no more be separated from the agent than the wave can be separated from the water or motion from the moving body. How, then, does the action of the agent produce an effect in the recipient? By arousing the latent forces present in the recipient into an action of their own; thereby the recipient is changed, and an effect is produced in it. "The action of a created agent is in the patient," as Mercier himself states in the reference given by himself.⁸

But if that is so, how can the action of the agent influence the recipient without *contact*, mediately or immediately? Since the force and its action cannot leave the agent, the lack of contact due to an absolute vacuum would make it impossible for the agent to affect the recipient. The force and its action need a *bearer*, and the vacuum, being nothing, cannot act as bearer of either force or action. Hence, the agent cannot influence the recipient under such conditions. If the action proceeding from the agent did not terminate in an object *present* to it, it would terminate in *nothing*, because a thing, with respect to a place where it does not exist, is equivalent to nothing in that place. In that case, however, *it could not act at all* in transient activity, and then no effect could be produced. But that is equivalent to saying that an 'action at a distance' is impossible. The supposition, however, is, that such an action is possible. Since to be 'possible' and 'impossible' is a contradiction in terms, and since a contradiction is metaphysically

impossible, it seems clear that an 'action at a distance' is *metaphysically impossible*.

The argument can also be formulated in the following manner. Action presupposes being (*agere sequitur esse*). But no being *exists* at a distance. Therefore, no being acts at a distance. The major premise demands elucidation and proof. Action has two phases: the exercise of the cause in the agent, and the dependence of the effect on this causality of the agent. The *exercise* of the cause is dependent on being; because, in so far as a thing lacks being, it is equivalent to 'nothing,' and 'nothing' cannot perform any action. Hence, in so far as a thing is restricted in its being, it is also restricted in its action. But the *dependence of the effect* on the causality of the agent is also dependent on this being; because, only in so far as a thing is present, can something be said to be dependent on it and sustained by it. Consequently, only where the being is present can the action be said to be present; and, since the active agent is not present at a distance from itself, neither can the action be present at a distance from the agent. But it is only where the action is, that the effect can be. Hence, action at a distance is impossible.

Mercier contends that such arguments really beg the question by presupposing the very point at issue. That is something which the student must decide. Most scholastics judge that the arguments are legitimate.

THE EXISTENCE OF THE AETHER

The *aether*, or *ether*, is a kind of imponderable matter far more subtle than that of visible bodies and is assumed to exist in all those parts of the universe not filled by ponderable matter. Aether, therefore, fills out the space between subatomic particles (electrons, protons, etc.), atoms, molecules, large aggregations of bodies, and the heavenly bodies. Since it is supposed to fill all interstellar space, it is the most widely diffused material substance known.

Experimentally, the existence of the aether has never been positively demonstrated. It is, however, a *postulate of science*. The vast stretches of interstellar space are, to the greatest extent, empty of ponderable matter. Even the spaces between molecules and atoms and between the planetary electrons and the nucleus of the atom are empty, and the distances between them are relatively very great. Every piece of matter 'attracts' every other piece of matter through *gravitational force*. Gravitation permeates the entire universe through all space. Similarly, *waves of radiation* traverse the universe in all directions from the stars. Without the presence of some universal medium of transmission, these phenomena are inexplicable — particularly, if one affirms the impossibility of 'action at a distance.'

Furthermore, the same sort of vehicle is required as the medium for *cohesion*, *chemical affinity*, electromagnetic *attraction* and *repulsion*, *mechanical force*, and for the *elasticity* which exists between particles; these particles do not touch, but remain at a distance. In order, then, to avoid action at a distance, these portions of matter must be

connected by a medium. This medium physicists term 'aether.'

Electrons, positrons, protons, and photons are, so far as scientists can judge in their present state of knowledge, the ultimate particles of ponderable matter. They are, however, always surrounded by *fields of force* and accompanied by phenomena of *wave action*. Evidently, then, they are completely enveloped by a universal medium which becomes agitated by these particles and reacts by means of fields of force and waves. Notwithstanding the corpuscular nature of electricity and light, the existence of aether thus still appears, from the standpoint of science, to be a *physical necessity*.

As to the exact nature and constitution of aether, little or nothing is known. This much, however, is certain: its structure cannot be molecular, but must be *continuous*. If the aether were molecular, the very purpose for which its existence is postulated would be nullified; because in that case it would consist of separate particles with space between them, and the problem of 'action at a distance' would not be solved. Such an aether is useless. Only an aether that is perfectly or at least imperfectly continuous can fill the requirements of a universal medium between particles and portions of ponderable matter which are separated by interspaces.

From these entitative and operative qualities with their respective activities we now pass on to a consideration of 'movement' and 'time,' two concepts always involved in bodily activity.

SUMMARY OF CHAPTER VIII

Qualities and *activities* are important properties of all bodies; they reveal indirectly the nature of a being.

1. *The Concept of Quality.* A quality is an absolute accident completing and determining a substance in its being and in its operations. Hence, there are two main types of qualities: 'entitative' and 'operative.'

2. *Entitative Qualities.* These qualities modify a substance in so far as it is a being for itself; they are more static in character, tending to stabilize the substance in its own being. The states which result from such qualities are *subatomic, atomic, molecular, and molar states*.

3. *Operative Qualities.* These modify a substance in so far as it is capable of activity and change; they are more dynamic in character, tending to influence and change things by action. An operative quality is a proximate accidental principle of operation, toward which (operation) it is specifically directed. There are two main kinds of activity or operation in this connection: 'transient' and 'immanent.'

4. *Transient Activities.* These are activities which tend to change another object, distinct from the agent, thereby making this object the term or goal of the acquired actuality. Transient activities may be *chemical*, when they change the chemical substances, or *physical*, when they change the qualitative states of substances, or *mechanical*, when they produce motion and effect a change of position.

5. *Immanent Activities*. By means of these a living being perfects itself and makes itself the goal for the acquired actuality. There are three main types of organic beings with specific kinds of immanent activity. *Plants* have vegetative functions: metabolism, growth and development, reproduction, and adaptation. *Animals* have sensory function: the somesthetic sense, taste, smell, hearing, sight, central sense, imagination, sense memory, instinct, and also *orexis* and power of locomotion. *Man* has intellection and volition; he is endowed with self-consciousness and is a person.

6. *Action at a Distance*. By this is meant action across an absolute vacuum, without any intervening medium of any kind. It seems to be *metaphysically impossible*. Actions and forces are accidents; as such they must inhere in a substance and cannot pass from one body to another. Hence, one body cannot influence another except by contact, either immediately or mediately. Since action presupposes being, and since no being exists through a distance, it follows that no being can act at a distance.

7. *The Existence of the Aether*. This is a *postulate of science*. The aether is necessary as a universal medium in order to account for gravitation, for the transmission of radiation, for the effects of cohesion, chemical affinity, electromagnetic attraction and repulsion, mechanical force, and elasticity, and for the existence of fields of force and wave action in the universe.

Chapter 9

MOVEMENT AND TIME

ANOTHER FUNDAMENTAL FEATURE OF ALL BODIES IS THEIR existence in *time*. Time, like the three dimensions of space, is a universal condition or modality of all things in the physical universe; for this reason it is often spoken of in our day as the 'fourth dimension' of bodies. And in fact, 'space' and 'time' are always found together; anything affected by space is also affected by time, and *vice versa*.

'Time' is most elusive and mysterious. We encounter it in everything we do and observe; and yet, in the very act of our scrutiny it seems to escape, for it is no longer present but past. Like space, time has always been a problem for philosophic minds. Since it is a species of 'duration,' it will be advisable to begin our investigation into the nature of time by a brief examination of 'duration.'

DURATION

Duration has a close relation to *existence*. It is impossible to conceive the idea of 'duration' without implying them idea of 'existence.' To say that a thing exists for a minute, a day, a year, or a century, is the same as to say that it has a

‘duration’ of a minute, a day, a year, or a century; and an ‘eternal existence’ is identical with an ‘eternal duration.’

It would be erroneous, however, to consider ‘duration’ and ‘existence’ as altogether identical in meaning. While it is true that ‘duration’ necessarily implies ‘existence,’ the reverse is not true: ‘existence’ need not imply ‘duration.’ God could create a being in one instant and annihilate it in the next. In this case the being has had ‘existence’ for one instant; but in no real sense did it have ‘duration,’ because it did not endure in its existence. For ‘duration’ a continued existence, no matter how short, is required. Hence, *duration* is defined as continued existence, or the *persistence of a being in existence*.

Time, since it is measured in instants, seconds, minutes, hours, days, and so forth, necessarily involves the concept of continued existence or ‘duration.’ We can, however, speak of ‘duration’ without in any way bringing in the concept of ‘time.’ The duration of God’s existence, for example, is termed eternity; it is, as the famous definition of *Boethius* (480—525) calls it, the complete and simultaneous possession of interminable life.¹ His existence is without beginning and end, without change and sequence, without past and future. God exists of necessity, and He possesses being and activity in infinite fullness without increase or decrease in an everlasting present. The measurements of time simply do not apply to the duration of God’s existence. God coexists with the thousands and millions of years of time, so that His eternal present corresponds without change to every moment of time as it flows from the future

through the present into the past: God's duration is an *eternal 'now.'*

Spiritual beings, since they do not consist of substantial parts and form no substantial compounds, have an existence different from that of physical bodies. They have a natural existence which, though it had a beginning, has no end. Having received existence, they cannot be destroyed except by annihilation. Such beings cannot suffer change in their substance, but there is succession in their states and activities. In some ways, therefore, they resemble the eternal, unchangeable existence of God and also the temporal, changing existence of physical bodies. Their peculiar species of duration is therefore designated as '*aeviternity*'; they are 'aeviternal.' *Aeviternity* is the duration in existence of a creatural being which of its nature is *substantially incorruptible* and immortal; it is also termed 'hypothetical,' 'relative,' or 'participated eternity.' Due to the fact that spiritual beings undergo changes in their activities and internal states, such as thinking and willing, it is a mooted question whether their existence should not be termed 'temporal' in character. At any rate, the concept of 'time' may be applied to them in a wider sense.

In a strict sense, *time* applies to the duration of *physical bodies*. Our concept of 'time' has been derived from our observation of the continued existence of bodies, due to the fact that we have an immediate awareness of our own body and other bodies in their movements and changing states. While, therefore, we do quite frequently speak of God and spiritual beings as if their existence were measured by the

standards of time, this is done in a figurative and *analogical* sense. This will become clearer as we progress in our investigation.

THE CONCEPT OF TIME

The notion of 'time' is common to all men of all times; it antedates philosophy. Philosophy attempts to evaluate this notion and to determine the nature of 'time.' To proceed logically, therefore, we must begin with the notion of 'time' as it is used in daily life.

'Time' is conceived as *successive duration*. Unlike space, time is not stationary and immobile; on the contrary, it moves onward continuously, and the 'march of time' is a phrase current in every language. Nothing can stop, retard, or hasten it, because 'time moves with an ever even pace'; its movement is steady, inexorable, unchangeable in progress and speed. Nevertheless, in opposition to this statement, 'time flies,' 'time drags,' 'the time is short,' 'the time is long,' 'the time of the race was reduced considerably,' and so on. It is viewed as something which embraces within its capacity all movements and activities of the universe, for we say that 'all things happen in time.' Like space, we conceive it as some sort of an *entity* preceding the creation of the world, as when we state that 'the world was created in time' or that 'the world could have been created at any earlier time'; and we also think of it as extending without limit into the future, irrespective of the future existence of the world, as when we use the expression 'time without end.' We thus give to it the

attributes of a *certain infinity*. On the other hand, it is considered to be altogether *finite*, because 'the time was one second, one hour, one day, one year,' etc. 'Time' consists of the 'past, present, and future'; still, 'the only time is the present, because the past is no more and the future is not yet.' Many contradictory statements are thus made about 'time.' What, then, is this mysterious, contradictory thing called *time*?

To a great extent, it will be noted, the properties of 'time' parallel those of 'space.' It is but natural, therefore, that the opinions of philosophers on the nature of 'time' resemble their opinions on the nature of 'space.' *Epicurus* viewed it as an entity and existence independent of the mind. *Gassendi* conceived it as a special sort of being, neither substance nor accident, totally different from the things and movements which exist in it. *Newton*, *Clarke*, and others, identified it with the eternity of God. *Descartes* looked upon it as a mere mode of thought. *Spinoza* made it an attribute of his pantheistic divine substance. *Kant* maintained that 'time' is a subjective, innate, *a priori* sense form of internal intuition, antecedent to all experience, which makes all things and experiences appear as occurring 'in time'; it is not an objective attribute of things-in-themselves and has no foundation in the reality of nature. His view finds an echo among many scientific philosophers of modern times, notably among the followers of the school of *Einstein*, where 'space-time' is interpreted in a large measure as being more or less a mental construct imposed on the universe.

S. Alexander and many adherents of the recent theory of 'emergent evolution' give an unusual meaning to *space-time*. It lies at the basis of the evolution of the universe. "Space-Time is the stuff of which matter and all things are specifications."

"The stuff of the world which is Space-Time I have also described as Motion, that is Pure Motion, before matter has been generated in it." "The world which is Space-Time never and nowhere came into existence, for the infinite becoming cannot begin to become . . . Space-Time does not exist but is existence itself, taken in the whole." "In truth, infinite Space-Time is not the substance of substances, but it is the stuff of substances. No word is more appropriate to it than the ancient one of hyle ($\upsilon\lambda\eta$). Just as a roll of cloth is the stuff of which coats are made but is not itself a coat, so Space-Time is the stuff of which all things, whether a substance or under any category, are made." According to this view, then, space-time is some sort of primordial, unformed, chaotic entity which eventually becomes, through evolution, every kind of specific being present in the universe; indeed, it even becomes mind and deity.

Bergson maintains that there is no real duration except in our internal (mental) states. We obtain the idea of succession, and thereby of time, in the world by introducing *spatial relations* into our states of consciousness. Real time, therefore, does not exist in the physical world; it is a purely mental product.

The *scholastics*, following *Aristotle*, maintain that 'time' is not a distinct entity or reality; it is a *conceptual entity with a foundation in nature*. Our concept of 'time' is based

on *movement* and *change* in ourselves and in other bodies. In so far as actual movements and changes occur in nature, the time involved in them is *real time*. There are, then, as many 'real times' as there have been, and are, and will be, actual movements and changes in the single bodies throughout the universe from its beginning until its end. The universe was created by God, and that not from eternity (we presuppose that here); hence, God could have created it earlier than He actually did. He could also have created a much larger universe, containing indefinitely more bodies than actually exist. There are, therefore, possible movements and changes which could, but never will, exist. The time involved in these possible movements and changes is *possible time*. The sum of all real time and all possible time, considered merely as 'time in general,' is *absolute time*. If we make a phantasm or image of this absolute time in our imagination and picture it as a kind of receptacle or stream in which all individual times, actual and possible, have a place, we have *imaginary time*. While 'time,' then, in the scholastic view, is not an entity independent of the mind, it is not a pure fiction of the mind, but has a foundation in reality, inasmuch as it is an abstraction derived from actual movement and change in nature. We accept this view, just as we accepted the scholastic view on the nature of 'space.'

TIME NOT A REAL BEING

'Time' is *not a real being* which exists in nature independent of the mind. The reasons are practically the

same as those which were adduced to show that 'space' is not a real being. Briefly, they are as follows.

Time, as we conceive it, extends *without limit* in the past and in the future. Since God is eternal, no limit can be assigned in the past or in the future in which God could not create bodies. Bodies, however, exist 'in time.' Hence, if time is a real entity, it must possess a *positive eternity*. Now, if time is without limit in the past and future, i.e., eternal, it must consist of an *infinite number* of present moments, because it consists of a series of successive present moments which flow continuously from the future through the present moment into the past. But an infinite number is impossible. Therefore 'time,' as a real being, is impossible.

Again, if time were a real being, it would be an entity existing itself and for itself; in other words, it would be a *substance* and, since it is not spiritual, *material* substance. Now, a material substance is a *body*. Time, however, is conceived as being in a continuous process of movement and change; hence, it would be a continuously moving and changing body. But moving and changing bodies are acknowledged by everybody to be 'in time.' Hence, 'time,' since it is a moving and changing body which exists 'in time' demands another absolute time in which to exist as 'in time.' This second absolute time, for the same reason, demands a third absolute time; and this process must be repeated through an *infinite regress*. That, however, again necessitates an infinite number, which is a contradiction in terms. 'Time,' therefore, cannot be a real being.

'Time' cannot be the *eternity* of God. God's eternity is altogether simultaneous and as such without a vestige of

change or succession, while time is characterized by continuous change and succession. Nor can it be an *entity* in the meaning of Epicurus or Gassendi, because such an entity, being eternal in duration, would involve an infinite number of successive moments. Nor can it be the *stuff* out of which all things in the universe are generated through evolution, as is postulated by the space-time of Alexander and others, because 'time' is conceived by everyone as something in *which* all bodies exist, but not *out of which* they are made.

From all this it follows that it is a philosophic error to consider 'time,' as we conceive it, to be a real being existing as such.

TIME NOT PURELY MENTAL

'Time' is not a purely conceptual being without any foundation in the realities of nature; on the contrary, it is based on definite occurrences of motions and changes actually taking place in and among bodies.

For one thing, we *experience* such movements and changes in our own being. Our being is not static, but dynamic. We are continually *doing* things. We develop and change in an active manner. We *move* from place to place. Our bodily and mental states *change* from hour to hour and from day to day.

We can no more doubt or deny these facts than we can doubt or deny our own existence. These realities, however, are not instantaneous in character, but gradual, *successive*, progressive. And therein lies the element of *time*, namely, a

succession of instants and moments which is measured in seconds, hours, days, and years. If these realities exist, time has a foundation in nature and is not purely mental and subjective in character. If time is a purely conceptual being, these realities must also be purely conceptual beings; but in that case, the testimony of consciousness is an illusion, and then all knowledge is an utter impossibility.

Science testifies to the actual *existence of the physical world*. And with the existence of this world there is also given the existence of physical *motion* and *change*. Elements combine to form compounds and then dissolve to form other compounds; this process of combination and dissolution goes on uninterruptedly. Bodies *move* from place to place, not instantaneously, but by passing over definite regions of space. The *earth* revolves on its axis once in every 24 hours and around the sun once in every 365 days. This motion is used as the standard of measurement for other motions, because it is uniform and continuous; it is our 'day' and our 'year.' The day is divided into periods of hours, minutes, seconds, and fractions of seconds, while the year is divided into months. But seconds, minutes, hours, days, months, and years are divisions of *time*. Consequently, 'time' is not a purely subjective construct of the mind, but is founded on the realities and occurrences of nature. To deny that time has a foundation in nature and to assert that it is a purely conceptual being, is tantamount to a denial of the existence of motion in the world and of the world itself. Such a denial, however, means the bankruptcy of scientific knowledge and of all knowledge.

In view of these facts, the contention of Kant, that our concept of 'time' is due solely to an innate, subjective sense form, anterior to all experience, is seen to be entirely arbitrary and unwarranted. Descartes' contention, that times is nothing but a mode of our thought, is also erroneous. And so, too, is the view of Bergson.

MOVEMENT AND TIME

In order to understand the true nature of time, we must have an understanding of movement, because the concept of time presupposes the concept of movement and is derived from it.

By *movement* we mean here *continuous change*. By 'change' we understand the transition of a thing from one positive state of being to another positive state of being. Three elements are required in a change: one state of being as the starting point; a different state of being as the ending point or goal; and a transition or passage from the one state to the other. Both the starting point and the goal are a condition of rest; the 'change' itself consists precisely in the transition or passage between these two points of rest. While the thing is still at the starting point, it is at rest; it does not change, and there is no movement. When the thing has arrived at the goal, it is again at rest; the change is completed, and the movement has ceased. It is only during the period when the thing passes from one state to the other, from the starting point to the goal, that change and movement occur.

This change must be uninterrupted, *continuous*. No gap or stop may intervene between the terminals of the starting point and the goal. If a stop occurred, so that the change were discontinuous at any point, that point would be the goal, the point of rest; the change would cease, and the movement would cease with it. Similarly, a change which is instantaneous, and not continuous, would involve no movement. 'Movement,' as the term plainly indicates, involves *successive stages* in the transition from one state to another, and that excludes instantaneous change.

Movement may be either *quantitative* or *qualitative*, inasmuch as there may be a continuous change either in quantity or quality. We have quantitative movement in *local motion*, namely in the passage of a thing from one place to another. This is the most common and most obvious type of movement, the one most readily associated with 'time.' The distance traveled and the time elapsed are universally associated, as when we say that 'the sprinter's time was ten seconds for the hundred yards,' 'the train made the run between Chicago and New York in sixteen hours,' 'the automobile made eighty miles an hour,' and so on. Qualitative changes or movements are *alterations* in a thing. Such alterations may be physical, as when iron is magnetized and demagnetized, or physiological, as when the human body turns from a healthy into a diseased condition, or psychological, as when the mind works out a problem through a lengthy process of reasoning. Alterations of this kind also have a reference to time, because they involve continuous change and 'take time,' although local motion is not present as the real basis of the

change. It would be an error, therefore, to consider time as being associated only with quantitative movement as observed in local motion; time is found in any continuous change in and among corporeal beings in the universe.

Bearing the nature of movement in mind, it should not be difficult to arrive at the correct philosophic concept of the true nature of 'time.'

THE TRUE NATURE OF TIME

All statements concerning 'time' contain the notion that it consists of progressive, successive movement. We must, then, begin with this general idea.

The notion of *time involves the notion of movement* We cannot think of time without thinking of movement of some sort. This is clear from the fact that we conceive time as being composed of past, present, and future; the present moves into the future, so that the future, moment after moment, becomes the present and, after it has become the present, passes into the past. But that indicates constant change, progression, succession, *movement*. Furthermore, the standards of *measurement* which we apply to time are all taken from movement. The fundamental units of time, as we know it and measure it, are the year and the *day*. Both, however, are taken from the local motion of the earth in its orbit around the sun and from its rotation on its own axis. These units of measurements are acknowledged by all as being most appropriate for the purpose of measuring and marking off time in its forward progression. But this would not be so if time itself did not consist of movement or had

not its foundation in movement. Consequently, time involves the notion of movement.

Time and *movement*, however, are not identical. A comparison of the two concepts will remove all doubt on this score. For example, local motion, which is a species of movement, may be vibratory, as in light, longitudinal, as in a speeding train, rotational, as in a revolving wheel, and reversible, as in a swinging pendulum. The progression of time has none of these variations and attributes; time, though intimately associated with local motion, never goes from place to place. Then, too, a movement may begin, proceed, stop, and begin and proceed again; but time goes on without interruption. Finally, movements are slow or fast, uniform or accelerated, while time moves onward at a steady rate and can never be hastened, retarded, or changed. It is true, of course, that we speak of 'slow time' and 'fast time' with respect to moving bodies, as in a race. What we really mean, though, is the *distance* covered in a given time, not the time itself. Ten seconds, or ten hours, or ten years, are *invariably the same*, considered strictly as intervals of time. Hence, 'time' and 'movement' are not identical.

Time is movement considered abstractly in its succession. The concept of time involves, as we have just shown, the concept of movement, but it is not identical with movement. There must, then, be something in movement which is the essence of time, without which there can be no time. Now, the one thing common to all types of movement is *succession*, the *before-and-after* of movement. But it is precisely this uniform succession of moments, with its

character of before-and-after, which constitutes the essence of that species of duration which we designate by the name 'time.' If, then, we remove from 'movement' the different varieties and the different rates of motion and change, and if we prescind from the manifold types of bodies which have movement, so that we retain in the mind nothing but *abstract movement* itself consisting of *uniform succession*, whether real or possible or absolute, considered in its forward progression with a character of *before-and-after*, then we have time. That is why we find 'time' not merely in local motion, but also in the changes of physical, physiological, and psychological states; they follow in true succession, with a before-and-after, and as such the concept of 'times' is verified in them: successive movement is present, but not local motion. This explains why we can notice the passage of time, when we are motionless and observe no motion, but concentrate our attention on the presence and succession of our internal thoughts and emotions.

Again, 'time' must consist of that by means of which alone we *know* it and can *measure* it; for the essence of a thing is known by its properties, and the measure must correspond in kind to the thing measured. A little reflection will show, however, that we obtain a *knowledge* of time only through the observation of movement or the succession of changes. When we are conscious of movement, we are aware of the passage of 'time'; but when we are unconscious of movement, we are also unconscious of the passage of 'time.' This is a daily experience. If we take a timepiece and watch the movements of the second and

minute hands move around the dial, we become almost painfully conscious of the progress of time, and then time seems to move very slowly; but if we are completely engrossed in thought or emotion, or if we are asleep or unconscious, so that movement escapes our observation, we are unaware of the minutes and hours, and then time seems to move very quickly. Similarly, the *measurement* of time is made by using some unit of motion or change as a standard: for example, we measure time by the movements of the stars, of the earth, of clocks, of water and sand, etc. Consequently, 'time' consists in the succession of movements or changes. Since, however, *concrete* movements and changes are conceived *in time*, time can only be movement in the *abstract*, considered as the *receptacle* of all movements.

Time, viewed as the abstract receptacle of all actual movements, past, present, and future, occurring in the existing universe or universes, is real time. Viewed as the receptacle of all possible movements which could, but never will, occur, it is *possible* time. And viewed as the sum of all real and possible movements, it is *absolute* time. Viewed as the receptacle of movements which have already occurred, it is past time; of movements occurring now, it is *present* time; of movements which will occur, it is *future* time. All features of 'time' thus receive an adequate explanation, when we conceive it as movement considered abstractly in its succession.

Time is based on continuous movement. A movement is continuous, when it proceeds without interruption, without coming to a point of rest. But that is precisely how we

conceive time, in the strict sense of the term, to be. Our concept of time is such that we view it as a movement which goes on and on, at a uniform rate, without a break or gap, from the beginning of the world until its end. It is a species of *duration*, and duration, as was pointed out before, is persistence in existence and as such means *continued* existence. Hence the movement on which the concept of time is based must be a continued or continuous movement. Movement stops, when a point of rest is reached an interruption in the movement, with the movement beginning anew after the interruption, really inaugurates a second movement distinct from the first: movement, of its very nature, thus implies continuity. And since time is abstract movement, we naturally conceive it as being continuous in its progress.

It must be remembered, however, that we do not always use the term 'time' in this strict sense. Frequently, we group a *series of interrupted movements* into a unit of time, so long as these separate movements are connected in some way as a whole of which they are the natural parts. A train, we say, takes sixteen hours to make the trip from Chicago to New York. The trip, of course, is not made without stops; but the entire trip is a whole which may be measured as a whole in terms of hours and minutes. In cases of this kind we sometimes distinguish between 'total time' and 'actual running time.' In the instance mentioned, the 'total time' of the trip is sixteen hours; the 'actual running time' is, let us say, fifteen hours and ten minutes, omitting the fifty minutes consumed by stops on the way. Taking time in the strict sense, there would be as many

'times' as there were runs from stop to stop over the entire route from Chicago to New York, because these runs alone are continuous in character. This brings us to the distinction between 'individual' and 'general' time.

Individual time is manifold; general time is one and uniform. By *individual* (particular, intrinsic) time we understand the succession inherent in any concrete movement taken by itself. This time is independent of any comparison with a standard unit of time such as a minute, an hour, a day, a year. If no creature existed but a single body, and if this body underwent a successive change, time would be there in this movement, although in this case no measurement of it could be made by comparison with other movements. And the same applies to any movement of any being in the world: it has its *own* individual (particular, intrinsic) time by the mere fact that it is a continuous movement, irrespective of the existence or movements of other beings.

By *general* (common, extrinsic) time we mean the successive movement of one thing taken as a standard according to which we *measure* the individual (particular, intrinsic) time of another thing. This standard of measurement is a matter of selection on our part. Such a standard must, of course, be one and uniform in character and not subject to appreciable variations; otherwise it would defeat its purpose. With us, this standard of measurement is the rotation of the earth on its axis once a 'day' and around the sun once in a 'year.' This is a natural division of general time, while the division of the year into twelve months, of the day into 24 hours, and of the hour

into 60 minutes, is arbitrary. Since the rotation of the earth on its axis and in its orbit around the sun is practically always the same, general time is uniform. The individual time inherent in a being is the reason why it can be measured and also the reason why it can be used as a standard to measure other individual times.

We are now in a position to understand *Aristotle's* definition of time as the *number of movement according to before-and-after*. It is the 'number' of movement, because we measure time by numbering the parts of the movement. These parts are not actual and separated, but potential, because the movement is continuous; consequently, the number of these parts is itself not actual, but potential. It is the number of 'movement, in so far as this movement is successive and continuous in its passage from a starting point to a goal; time is found only in this kind of movement. It is the number of movement 'according to before- and-after.' This is obvious from the fact that the movement, which we call 'time,' is gradual and successive and is realized bit by bit, so that the parts of the movement follow each other in a steady flow; in other words, these parts stand to each in the relation of 'before' and 'after.' That is why *St. Augustine* says: "If nothing went by, there would be no past time, and if nothing came, there would be no future time: the present, however, if it always remained present, would not be time, but eternity.

THE REALITY OF TIME

Time, as we have proved, cannot be a real entity existing in nature, independent of the mind. Such an entity would be a contradiction. It can, therefore, exist formally, i.e., precisely as conceived, only in the mind: it is a *conceptual*, mental being. Time, however, is not a mere fiction of the mind. On the contrary, it has its ground, its *foundation*, in the reality of the movements occurring in nature. These movements and changes are real and objective, whether our mind adverts to them or not. Bodies move and change in a continuous progression and succession as actual events in the universe, independent of our observation and thought. And since our concept of 'time' is based on, and derived from, these movements and changes, time is not a purely conceptual being, but a *conceptual being with a foundation in nature*.

Time is an *abstraction* made by the mind from the concrete movements actually occurring. Time consists in its totality of past, present, and future. But the past is no more, and the future is not yet; the only part of this totality which actually exists is the present moment. To grasp this totality of past, present, and future *as to totality*, a *mind* is required which is capable of thinking of all three parts simultaneously and of forming them into the unity of this totality. Time, therefore, precisely as 'time,' is a product of the mind obtained through the process of abstraction and exists as such only in the intellect.

As was just stated, the only one of the three main parts of time which actually exists is the *present*. The present has *no parts* and *no measurable duration*: it is the *indivisible moment* which connects the past and the future. Time is

essentially a forward movement, a progressive succession. Unlike space, time has no parts which are simultaneously coexistent; the parts of time succeed each other in a before-and-after as past, present, and future. If there were parts in the present, it would be divisible into these parts. These parts, however, follow each other in a relation of before-and-after, and that excludes the simultaneity of these parts. Let us suppose, for the sake of argument, that the present has two parts; for it certainly cannot have less than two, if it has any parts at all. Since these two parts are such that one succeeds the other, we have the following result. If the first part is existent, the second cannot coexist with it, because the second part succeeds the first and will be in the future; and the future is as yet nonexistent. If the second part is existent, the first will already be gone, because it must precede the second in the flow of time; it will thus belong to the past, and the past is nonexistent. Hence, since the essence of time consists in succession and not in simultaneity, the present can have no parts; as such it is *indivisible*. The duration of the present must then also be indivisible, so far as before-and-after is concerned; but if so, this duration is not measurable. Consequently, the present is an indivisible moment, an *instantaneous now*. It would, therefore, be more in accordance with strict terminology to say that the parts of time are the past and the future, while the present is the *point of termination* for past and future, situated between the two as the end of the one and the beginning of the other.

It must be remembered, though, that the *present* is often taken in *different meanings*, when used in ordinary

conversation. In its widest sense, the 'present' may mean anything from a second to a century or more. In this sense we speak of the 'present hour,' the 'present year,' the 'present century,' the 'present era.' In a *wide* sense, the 'present' signifies a very short span of time in proximity to the instantaneous now. It is in this sense that we *usually* speak of the present. This is due to the fact that a body in motion can be perceived by us as traversing a definite field of space; its progress can be followed as it moves on its way, as when we see a hand draw a line or an airplane cross the sky. Most people estimate the present to be a matter of one or some seconds. In its *strict* and philosophic sense, the present consists of an indivisible instant connecting the past and future.

After this examination into the nature of time in its various phases, we can define time in general as the duration of a mutable being in so far as it is mutable, or *as movement considered in its succession according to before-and-after*. 'This definition applies to past, present, and future time, to intrinsic and extrinsic time, to real, possible, and absolute time. Aristotle's definition applies more to extrinsic time than to time as such.

EXISTENCE IN TIME

In order that something *exist in time*, it must be *affected by time*. It is affected by time by being a part of time or by being measurable in terms of time.

Those realities are properly said to exist in time from which the notion of time is derived. Local motion, therefore,

exists in time, because local motion manifests most clearly the successive movement peculiar to the concept of time. In all probability it was from local motion that the concept of time was abstracted by man and then generalized. All *successive changes* exist in time, even though local motion be not involved. Such are the qualitative states of things. They, too, can be measured in terms of time, because they are brought about through a process of successive development having a beginning, a transition, and an end; their movement can be measured according to a definite before-and-after. All *periods of rest* in corporeal beings exist in time, but indirectly. They are the terminations of movement; since movements belong properly to time, their terminations belong there also. They are measured indirectly by the movement of some other thing. If one thing is in a state of motion for two hours, and another thing is in a state of rest during this same period, it is in a state of rest for two hours; the same units of measurement apply to both, and both must, then, exist in time.

Movements, of course, have no independent existence of their own; they are the movements of some *thing*. There is movement, because bodies move. Hence, bodies properly exist in time, because they are the bearers of motion and change. And since the universe is the assemblage of all bodies, the *universe* properly exists in time. Time, then, is proper to the universe and to all beings which are a part of the universe. Man, too, since he is a corporeal being, exists in time.

The question has been raised whether *substances*, and especially the spiritual soul of man, can be said to exist

properly in time. Substances are permanent realities; the changes which take place in them seem to affect only their accidental states and conditions. It is true that substances are permanent realities; but this permanence is only relative, not absolute. *Inorganic* substances, when they become a part of living tissue in an organism, certainly change from nonliving to living; while in the organism, they participate in the successive progress peculiar to the function of the organism, and as such are measurable in terms of time. Even outside an organism, in their strictly inorganic field, they enter into chemical compounds in various ways, and, if modern physics is correct, are subject to many changes within their atomic structure. Such changes are gradual, successive, and belong to time. *Organic* substances, since they are generated, develop to maturity, and die, certainly undergo change and movement. Hence, they also must be adjudged as belonging properly to time. Corporeal substances are relatively permanent, when compared to the manifold accidental movements which occur in nature but they are not absolutely permanent.

The *soul of man*, being spiritual, is naturally incorruptible and unchangeable in its essence. Taken alone by itself, it is not measurable in terms of time. When we consider, however, that the soul, in this life on earth, does not exist except as one of the two substantial parts which constitute man, and when we consider that man, as man, is an organic being subject to development, change, and death, then we must say that the *total man* (and that includes the soul) exists in time.

This concludes our investigation into the *physical nature* of bodies. Science has been of considerable help to cosmology in arriving at a better understanding of the bodies which build up the universe. All bodies are characterized by matter and energy. There are about 92 elements, and these are the fundamental types of existing bodies. All elements, however, have the same structural components, namely, electrons, protons, and neutrons, etc. Contrary to previous scientific and philosophic pronouncements, elements are not immutable; some disintegrate spontaneously and most can be transmuted artificially. The structure of the elemental atom is still the subject of scientific theory and speculation; the evidence, though probable, is not conclusive. Then certain universal features of bodies were discussed, namely, extension and quantity, place and space, quality and activity, movement and time.

This first part of cosmology forms the groundwork which must serve as the foundation for an intelligent examination into the essential constitution of bodies. To determine, if possible, the essential constitution of bodies, will be our next task.

SUMMARY OF CHAPTER IX

Time is a universal condition or modality of all things in the universe.

1. *Duration* is persistence in existence. God's duration is 'eternity'; that of spiritual beings is 'aeviternity'; that of physical bodies is 'time.'

2. *The Concept of Time*. Time is conceived by all men as successive duration; as a sort of entity that extends without limit in the past and in the future, containing all shorter periods. Some philosophers view time' as an entity existing independent of the mind; others, as a purely mental being; the scholastics, as a conceptual being with a foundation in nature. According to this latter view, 'time' is an *abstraction* derived from *movement*. The time involved in actual movements in the world is real time; that in possible movements, is possible time; the sum of real and *possible* time is *absolute* time.

3. *Time is not a real being*. Time, as we conceive it, extends without limit in the past and future. If it is a real being, it possesses *positive eternity*. That, however, involves an *infinite* number of successive moments. An infinite number, however, is impossible. If it is a real being, it must be a material substance, a body which changes continually. Now, changing bodies are conceived as being 'in time.' Hence, a second 'time' is required to contain the first; a third is required for the second; and so on, in an *infinite regress*. An infinite regress, however, necessitates an infinite number; and that is a contradiction in terms.

4. *Time Is Not Purely Mental.* It has a foundation in nature, namely, in the motions and changes occurring in and around us. We experience such motions and changes in ourselves and in other bodies. *Science* testifies to the existence of such motions and changes in the physical world. Time is divided into days and years, depending on the movement of the earth. Hence, our concept of time has a foundation in the realities of nature and is not a purely mental product.

5. *Movement and Time.* Movement is *continuous change*. This may be either the quantitative change of 'local motion' or the qualitative change of states in 'alteration.' Both types of change are basic to our concept of time.

6. *The True Nature of Time.* Time involves the notion of movement, because time consists of the past, present, and future, and the future moves through the present into the past. The standards of measurement which we apply to time are taken from movement, namely, from the rotation of the earth on its axis and around the sun. Time and movement, however, are *not identical*; movements vary, while time is always uniform.

Time is movement considered *abstractly in its succession*. The one thing common to all types of movement is 'succession,' the 'before-and-after' of movement; and that, too, is the essence of time. Time must be that by means of which alone we know and measure it; but that is movement. Time is based on *continuous* movement. Individual time is manifold; general time is one and uniform.

Aristotle defines time as the 'number of movement according to before and after.'

7. *The Reality of Time*. Time is an *abstraction* made by the mind from the concrete movements actually occurring. As such, it is a mental product which exists only in the mind. Time consists of the past, present, and future, and of these only the *present actually exists*. The present has no parts and no measurable duration, it is an indivisible moment.

8. *Existence in Time*. That exists in time which is affected by time, i.e., which is either a part of time or measurable in terms of time. The things that exist properly in time are local motion, successive changes, periods of rest, all bodies in the universe.

PART III

**THE ESSENTIAL CONSTITUTION
OF BODIES**

Chapter 10

THE PROBLEM OF BODILY ESSENCE

IN ORDER TO APPROACH THE PROBLEM OF THE ESSENCE AND constitution of bodies in an orderly manner, it was necessary to settle certain preliminary questions concerning the *physical constitution* and the *general properties* of bodies. Science has supplied us, and still supplies us, with a wealth of information which, though incomplete, should be very helpful to the cosmologist as a point of departure for philosophic speculation regarding their ultimate essence and constitution. Without this scientific knowledge pertinent to the problem, the cosmologist runs the serious risk of building theories which lack the proper foundation in facts. Our first step, therefore, was an investigation of matter and energy, the elements, the components of atoms, the transmutation of elements, and the structure of matter. Our next step was an examination of the general properties of bodies, namely, quantity and extension, place and space, quality and activity, movement and time.

The scientist is satisfied when he succeeds in discovering and describing the physical components of bodies, their properties and behavior; that is as far as observation and

experimentation can lead him in understanding their constitution. The philosopher, however, finds a problem which lies deeper than this scientific aspect of material substance. This is the *essence or essential constitution of bodies as such*.

THE QUESTION OF SUBSTANTIAL CHANGE

Man's knowledge of the universe and its workings is acquired piecemeal; as a consequence, this knowledge is incomplete and inadequate, because the universe is a very complex reality both in the vastness of its cosmic construction and in the minuteness of its atomic constituents. It would be presumptuous to think that all scientific knowledge of today is absolutely certain and no longer subject to revision; and it would be equally presumptuous to think that this knowledge is altogether provisional and erroneous. Many facts have been established *beyond reasonable doubt*, and it is hardly possible that future investigation will overthrow them. These facts the cosmologist must accept as true and use as the foundation of his speculations. Any other procedure would be illogical. Facts must not be denied and theories must agree with facts. This must be the supreme principle of guidance for scientist and philosopher in their quest for truth; *for truth*, not the support of pet theories, is the goal of all research and speculation.

First of all, we accept the *existence of individual bodies*. Their existence cannot be denied except under the supposition that all knowledge is illusory; and that would

mean the bankruptcy of all science and philosophy. These bodies consist of *atoms* which are the ultimate units of *elements*. The exact number of elements is a matter of minor importance; the number, however, is rather large and should be about ninety, according to all indications. Each element is a distinct *type*, with sharply defined properties and activities, enabling the elements to be recognized, distinguished, and classified. All *elements* consist of positively charged, massive *protons* and of negatively charged, relatively mass-less *electrons* in equal proportions, so that they are electrically neutral in the normal state. *Fractionation* of the mass and electric charge of the protons and electrons is unknown; hence, it is safe to say that fractionation never occurs. Neutrons also exist in atoms; but whether they are uncharged masses or closely packed protons and electrons, is a disputed question.

The elements are subject to *disintegration* and *transmutation*. This happens spontaneously in the radioactive elements and is produced artificially in most elements through bombardment with atomic and subatomic particles. New elements arise in the process in many instances. The elements, therefore, are neither altogether stable nor immutable; they can and actually do undergo radical changes in their constitution.

The atoms of the various elements combine in manifold ways to form *chemical compounds*, and their reaction in combining is accompanied by the emission, absorption, and transformation of energy. The changes effected thereby are profound; the compounds differ considerably from their component elements in properties and activities.

Atoms, whether free or in compounds, are not inert, dead portions of matter. They are endowed with active *energies* and *forces*. These are the agencies which bring about chemical, physical, and mechanical changes among bodies. While it is true that the activity of energy is always accompanied by a certain amount of mechanical motion, and while it is also true that all types of energy can eventually be transformed into mechanical motion, it is no longer admissible to consider energy merely a variant of mechanical force or motion. Energy is a quality of matter as distinct as quantity, and qualitative changes are as real as quantitative changes. Furthermore, qualitative changes play a far more important part in the evolution of the world than quantitative changes.

No one would think of denying the *existence of real change* in individual bodies and in the universe at large. The fact is too obvious. But this brings the cosmologist face to face with one of the most profound problems of philosophy and science.

Are these changes accidental or substantial? By this is meant: Do these changes affect only the quantity and quality of physical bodies, leaving their underlying substance (essence) intact, or do they affect the substance (essence) itself, so that a new substance (essence) emerges as the result of such changes? If changes are accidental and the substance remains unchanged, the problem is quite simple. But if changes are *substantial*, a very difficult problem arises. It is evident that bodies are never *annihilated* in the process of chemical changes. Something of the *old* body survives in the *new*; something passes

through the entire process of chemical change and is present in the new substance just as it was present in the old substance. And yet, if substantial change is a fact, something new *in the line substance* must have originated in the process, or it would not be a 'substantial' change with a 'new substance' as the outcome. Just what, precisely, is the old part and what is the new part in a body after such a substantial change has taken place?

Chemists frequently state that a *new substance* arises as the result of chemical reaction, when elements combine to form a compound, or when compounds are dissolved into their component elements, or when compounds react among themselves and new compounds are thereby generated. What is the meaning of the phrase 'a new substance'? Do they mean that there is nothing more than a *regrouping* of the elements, so that the component elements retain their *full identity* in the compound? In that case, it would hardly be justifiable to speak of a 'new substance' in a philosophic sense; since the elements remain essentially and substantially identical before and after the change, the change can be only an 'accidental' one. A real 'substantial' change must be the *transition of one kind of substantial entity into a different kind of substantial entity*. In that case, however, the elements, when entering into a compound, must be essentially and substantially altered, so that they lose their former identity in becoming a new substance (essence). Is this the kind of change which occurs in chemical reaction?

To illustrate, Oxygen and hydrogen combine to form water. The properties of water are decidedly different from

those of oxygen or hydrogen. Does this indicate that both oxygen and hydrogen have ceased to exist in the compound, having lost their essential and substantial identity as oxygen and hydrogen, leaving in their place a new single entity, water, which is essentially and substantially different from them? Or, does it merely indicate that the qualities of oxygen and hydrogen have 'tempered' each other in mutual reaction, so that oxygen and hydrogen, although they are qualitatively altered, are still present in their essential and substantial identity, 'water' being nothing more than oxygen and hydrogen in close combination acting as a unit? The first interpretation represents a 'substantial' change; the latter interpretation, an 'accidental' change. 'Which is the correct interpretation of the fact of this reaction?

Another illustration. Chemicals from the soil are absorbed by a plant and changed into protoplasm and cell tissue, thereby becoming an integral part of the plant. They now participate in the vital functions of metabolism, growth and development, reproduction, and adaptation. The same chemicals, when assimilated into the animal organism, participate in the vital functions of sensation. While in the organic structure, they form compounds totally different from those which they are capable of forming in the inorganic state, as can be seen in carbohydrates and proteins. In other words, these chemicals have changed from nonliving to living substances. Can one maintain that, for example, carbon and hydrogen retain their identity as carbon and hydrogen in the organic compound and are merely changed in an accidental way? Or, are the living protoplasm and tissue of an organism essentially and

substantially different from that of the inorganic elements of carbon and hydrogen, the latter having lost their identity in a higher form of existence? In the one case or in the other, there would be respectively, an 'accidental' or a 'substantial' change. Naturally, if living substance is essentially different from nonliving elements, then the change which occurs when *nonliving* elements become *living* protoplasm and tissue is a substantial change in the strict sense of the term. With regard to the formation and dissolution of chemical compounds, there is far greater uncertainty about substantial change, because chemical reactions take place entirely on a purely inorganic plane.

The question of accidental or substantial change applies with equal force to the *atoms* and *elements* themselves. They are complex structures, built up from electrons, protons, and neutrons. Do these subatomic particles *retain* or *lose* their essential and substantial *identity* when they unite to form atoms and elements? Or, are atoms and elements simply *dynamic systems* which act as *functional units*, in which electrons, protons, and neutrons remain essentially and substantially intact? Do these particles remain *discrete* and separate entities at all times, or do they coalesce into a *continuous* substance in atoms and compounds? In fact, are there any strictly continuous substances in the universe among ponderable bodies, if we except these ultimate components?

The question concerning the fact of substantial change, it will be noticed, affects our entire interpretation and understanding of bodies and their processes throughout

the physical world. We must, therefore, seek a solution of the problem of substantial change.

THE QUESTION OF BODILY ESSENCE

More profound than the problem of substantial change is the problem of the *essence of bodies*. These two problems are intimately related.

By *essence* we understand that ultimate reality in a being which makes it to be what it is and distinguishes it from other beings. In so far as the 'essence' of a thing is the ultimate reality in it, it is the *substance*, because thereby it exists in itself as an independent being and does not need another as a subject in which to inhere and exist. For the same reason the 'essence' of a thing must be the ultimate source and principle from which all properties and activities of the thing are derived; looked at from this standpoint, the essence is called the *nature* of a being.

Every individual, unitary, natural body has an essence or nature which is the ultimate explanation of all that it is, has, and does. By a *natural body* we understand a body which has a *single nature* or *essence* and is an *individual substance*, so that it is a *real unit* in the order of being and operation. A plant, for example, is a 'natural body,' because all the organs and cells, notwithstanding their variety of functions, form an organic whole and work together for the benefit of the plant as a unit. A machine, on the other hand, is not a 'natural body,' because the single parts, though arranged according to a plan, have an independent entity of

their own and act in unison only through an extraneous force.

Essences are not all the same, for the reason that the bodies themselves are not all the same. All bodies fall under one of two widely divergent classes, *living* (organic) or *nonliving* (inorganic). Living beings appear in three distinct types: plants, animals, and men. There can be no reasonable doubt that the essence of plants, animals, and men belong to entirely different *species*. Vegetancy, sentiency, and rationality are so fundamentally diverse that they can have their source only in essences which are specifically different. Even among plants and animals there exists such a diversity of types that the specific difference of their essences can be safely maintained; we are, however, not concerned at present with these details. This much is certain: every single plant, animal, and man is a 'natural body,' an individual substance and unitary essence. In our own case, this is clear from the indubitable testimony of our consciousness, which bears witness to the fact that we are a single substance and nature, with a single principle of action dominating our whole being as a unit. A moment's reflection shows that we refer all our activities to the 'Ego': *I eat, I grow, I see, I hear, I think, I will*. This proves the natural unity of our being. And since animals and plants manifest a similar unity of action and behavior, they also must be 'natural bodies,' possessing a natural unity of being. This means that every organism, no matter how complex in function and structure, must be a single essence.

The difference between *living* and *nonliving* bodies is much greater than that between plants, animals, and men. All organisms have this in common that they are characterized by 'immanent' action. Inorganic bodies, however, are on a much lower level of being, since they display only 'transients action. Left to themselves, and acting in virtue of their natural forces, the inorganic elements are incapable of forming compounds which are specifically organic. In the organism, it is true, the elements form organic compounds and participate in vital functions; but when the organism 'dies,' the elements revert to their lower level of being again and seek to dissolve into inorganic compounds characteristic of their previous state. Evidently, then, organic and inorganic substances have a totally different kind of essence. What is this *essence*?

It would seem that the *atoms* of the *various elements* are the physical units, the 'natural bodies,' of the inorganic world, each element having a specific essence, distinct from that of the others. Each represents a type with characteristic properties and activities. However, as we shall see, this opinion is fraught with weighty difficulties, especially when we consider the modern views on the structure of the atom. More so than the atom, perhaps, the electron and proton seem to be essentially different; unfortunately, however, they appear to be 'parts' of bodies rather than bodies themselves. Inorganic bodies do not show the unity of being and action, which manifests a single essence, so clearly as the organisms do. Whatever may be our final decision as to what are the 'natural bodies' in the inorganic world, there can be no question about the fact

that such 'natural bodies' exist and have an essence which is the individual, unitary, natural source of their being and operation. Somewhere they must exist, whether in the chemical compound, or in the atom of the elements, or in the electron and proton. It may be that all of these, or only the one or the other, are 'natural bodies' with a single fundamental essence. That is another of the problems which the philosopher seeks to solve.

THE QUESTION OF CORPOREAL CONSTITUTION

All this leads inevitably to the question: *What is the ultimate constitution of natural bodies?* In other words: Wherein does the essence of natural bodies consist? How is this essence constituted in its final analysis? What makes a natural body to be a natural body?

The characteristic feature of every natural body is its *unity of being and operation*, revealing a single, individual, unitary essence or substance as the ultimate source of its properties and activities. One cannot overlook the fact, however, that natural bodies are the result of *composition*. By 'composition' we understand the union of two or more parts into a whole or unit; such a being is a 'composite' being. It is in opposition to a 'simple' being, which is one that has no parts into which it can be divided. A spiritual being is simple; a material body is composite, because, at the very least, it consists of internal quantitative parts. Even an electron or proton has dimensive parts in this sense and is, therefore, composite. Atoms, since they are formed from electrons and protons, are also composite. Chemical

compounds are built up from the atoms of elements; they, too, are composite. Plants, animals, and men possess complicated structures consisting of many parts; every organism, therefore, is also composite. It follows, then, that every body is affected by composition, because it is composed of parts united into a whole or unit.

This fact presents a serious problem. How can a number of parts make a unit or whole? How can 'one' be 'many,' and 'many' be 'one'? How can diverse components form a single essence and substance, a 'natural body'? How can we explain the individual function of each cell in a living being, the function of a group of cells in an organ, and the harmonious action of all cells and organs in the unity of the organism as a whole? Is this unity of composition in bodies merely a fancy of our mind, or is it a natural fact? If a fact, what is the *principle of unity* amid all the *diversity of parts*? What is the *constitution* of this essence, making it a unit of being and operation, notwithstanding the quantitative and qualitative difference of its components?

Furthermore, there are features in every material substance which are in *apparent contradiction* to each other. All bodies consist of matter and as such have quantitative dimensions. Matter tends to *spread out* into space; it involves a side-by-side-ness of internal parts in three directions. Yet there is a definite *limitation to the diffusion* of matter through space. What is it in a body that limits the diffusion of quantity and holds the extensive parts together, so that all bodies, living and nonliving, attain a unity of mass and volume? Matter is *divisible*, though actually *undivided*. The very fact that a body consists of

internal material parts which are different in their reality means that they can be divided and separated from one another. These parts, however, are actually a unit, tend to remain together as an undivided whole, and resist division. What keeps them united into a whole, although the composition of material parts would seem to favor division and separation? Bodies possess *inertia*, in virtue of which they are indifferent to rest and motion. Nevertheless, *motion* is one of the predominant factors in the universe and is present in the electrons, atoms, molecules, and larger masses. What accounts for these opposing tendencies toward rest and motion? All material substances are characterized by *quantity* and *quality*. Quantity is inactive, static; quality is active, dynamic. Because bodies are composed of matter, they resist change; because they have energy, they effect change and are subject to change. Whence these conflicting properties? How can we harmonize the apparent contradiction which lies in the very essence of a body?

The conclusion seems inevitable that there must be a *composition in the ultimate constitution* of natural bodies. The essence of every natural body apparently demands two fundamentally distinct *principles* in its constitution. But this would introduce a dualism into the essential constitution of bodies which in its very concept would seem to destroy the unity and singleness of essence which it is supposed to explain. Natural bodies are a unit of being and operation; then how can they be constituted of two more or less opposing principles, one active and one passive? How can substantial unity arise out of an essential dualism?

On the face of it, it would seem more logical to accept a *single, fundamental principle* of essence in natural bodies. We are all familiar with the idea of matter as this principle of essence. Scientists and philosophers in general accept matter as belonging to the essence of bodies. Why, then, accept a double principle, when one seems sufficient? Many philosophers, however, maintain that matter, being by nature static and not dynamic, is inadequate as the ultimate source and principle of the activities manifested by bodies. For this an active principle of essence is required. In consequence of this, other philosophers place the ultimate principle of the essence of bodies in *force or energy*. However, while force or energy seems a good explanation of the activities of bodies, it apparently fails to account for quantity, extension, inertia, and the passive state of bodies.

How, then, are we to conceive the fundamental essence of natural bodies? As a single reality? As a double reality united into a substantial unity? As a multiple reality which is merely an aggregate and possesses no substantial unity at all? What is the ultimate constitution of bodies?

The problem has perplexed the minds of philosophers from the beginning. A short sketch of the history of the problem should be of assistance to us in appreciating its proposed solutions.

EARLIEST SOLUTIONS

From the very beginning of philosophy among the Greeks, the problem of the origin and nature of bodies occupied the mind of the thinkers. Philosophy began with this problem.

Thales (about 620—546 B.C.) taught that all things derived their origin from water! *Anaximander* (born about 610 B.C.) placed the originating principle in the 'boundless,' some sort of material base unlimited in extent, similar to our concept of space. *Anaximenes* (died about 528 B.C.) held that 'air' (mist, vapor) is the fundamental substance, infinite in quantity, from which all things are made. These early philosophers were *animists* or *hylozoists*, i.e., they considered this ultimate substance to be inherently endowed with life, thereby destroying the specific difference between living and nonliving beings. *Heraclitus* (born about 530 B.C.) maintained that 'fire' (invisible warm matter) is the primitive substance from which, through a constant process of 'quenching' and 'kindling' (condensation and rarefaction), the world and the bodies in it are made and to which they return in eternal change. It should be noted that in these primitive and groping attempts *one single uniform substance* is assumed as the basic principle of bodily essences. Then a different trend appeared in Greek philosophy. *Empedocles* (about 490—350 B.C.) postulated four 'roots' or elements as the basic substances of the world: *fire, air, earth, and water*. They are primitive, indestructible, and homogeneous. Qualitative change does not occur. The seeming generation and decay of bodies is due to a mechanical 'commingling' and 'separation.' This process is brought about through an outside *force* by means of 'love' and 'hatred' (attraction and repulsion). This is a philosophy of mechanism. According to *Anaxagoras* (about 500—430 B.C.), the world in the beginning consisted of an indeterminate mass of extremely

fine particles of various substances (gold, iron, flesh, etc.), which were finally formed into definite bodies through the action of mind. This 'mind' is more in the nature of a force, but it is simple and possesses all knowledge and power. It does not enter into the constitution of things. This doctrine of 'mind' in nature is a distinct advance in philosophic thought, because it is the first intimation that something more than matter is required in order to account for the origin and constitution of bodies.

We now come to the *Atomists*. The founder of atomism is *Leucippus*, of whom practically nothing is known. *Democritus* (born about 460 B.C.) distinguished between the 'full' and the 'void,' both of which are existing realities. The 'full' consists of an infinite number of indivisible bodies or *atoms*, differing in shape, order, position, and magnitude. Due to their difference in magnitude, they are of different *weight*. All atoms fall through the void, through the sheer mechanical agency of their weight; since they are of unequal weight, they have unequal velocities. In the course of their descent the heavier atoms strike against the lighter ones, inducing a whirling *motion*. Thereby some atoms unite and others separate, and this explains the formation and decomposition of bodies. There is no design in all this; only mechanical necessity and casual concurrence. This is a philosophy of mechanism and materialism in its crudest form.

A new school of thought came into being with *Socrates* (469—399 B.C.). He was the first to clearly recognize the fact that in all things there is something relatively permanent amid qualitative changes, and this something is

their *essence*. This unchangeable essence can be expressed in a definition or idea of the thing. It is only through the idea or concept of a thing that we arrive at a real and lasting knowledge of it. *Plato* (about 427 or 428—347 B.C.) developed the Socratic 'idea' in an extreme and ultra-realistic fashion. For every corporeal being, for every kind of being, for every essence, there exists a necessary and immutable *Idea*. These Ideas exist for themselves in a separate world. Concrete things and realities are but partial, incomplete, and inadequate manifestations of these Ideas; Ideas alone have full reality and being. Corporeal substances are configurations of the four elements (water, air, fire, earth), and these configurations are brought about by the world soul. Concrete things are *phenomena* which partake of the Idea by *imitation*; they are copies of the Ideas which are their prototypes. The universe is a living animal endowed with an intelligent soul.

ARISTOTLE'S SOLUTION

It remained for the genius of *Aristotle* (384—322 B.C.) to propound a solution of the problem of bodily essence and constitution which is truly monumental. He was without a doubt the most scientific man of his age. Rejecting Plato's noumenal 'world of Ideas' as fanciful, he sought the proper understanding of corporeal beings in these beings themselves.

Aristotle accepted the four traditional elements — fire, air, water, and earth. The sublunary or earthly bodies are composed of these. To these four he added a fifth element

or essence — aether. All celestial bodies, the stars, consist of this pure essence and are unchangeable and incorruptible; in this he was, of course, mistaken. Some Greek philosophers had maintained that change is merely apparent; everything is unchangingly permanent. Others claimed that nothing is permanent; everything is in a process of unceasing change. Both views, as Aristotle pointed out, are partly right and partly wrong. Bodies undergo *substantial change*, but there is an underlying reality in bodies which remains permanent throughout all changes. When elements combine into a compound, the compound has a *specific essence* distinct from the specific essences of the constituent elements; and when a compound is dissolved into its elements, the compound loses its specific essence, while the specific essences of the elements are revived through the change. Bodies are both potential and actual, static and dynamic, quantitative and qualitative, passive and active. Because of this double aspect of their being, they are capable of giving and receiving new actualities, of effecting change and suffering change.

Change is fourfold: local motion (*φωρά*), quantitative increase and diminution (*αὔξησις* and *φθίσις*), qualitative alteration (*ἀλλοίωσις*), and substantial generation and corruption (*γένεσις* and *φθορά*). The latter is substantial change in the strict sense, and it takes place when elements form compounds ('generation') and when compounds are decomposed into elements ('corruption'); the generation of one body always implies the corruption of another or of others, and vice versa. In the process of substantial change

bodies are not annihilated; they are *transformed* from one kind of essence (substance) to another kind of essence (substance). Something is lost by the old bodies in the process, and something is gained by the new; but something of the old passes over into the new unchanged. There are, then, two *substantial principles* which constitute a body and are its essence, and of these one is passive and one is active. The passive principle is taken into the new body unchanged, while the active principle of the old body vanishes and is replaced by another active principle in the new. The passive principle is *matter* (ύλη). It is the part which is the common substrate of all bodies, and is characterized by absolute potentiality and indeterminateness; it can become any kind of body, depending on the active principle which determines it. The active substantial principle Aristotle called the *form* (μορφή). This is the distinctive part in each body, the active and determining principle which unites with primary matter and makes a body to be this or that *specific kind* of body. It is the substantial form which is gained or lost in substantial change, while primary matter always remains. Every body, therefore, is essentially constituted of two incomplete substantial principles, matter and form, and the union of the two makes a *complete specific substance*. Neither is sufficient of itself to be a body, because each is an incomplete substance; each requires and complements the other, and it is in the union of both that the essence of the 'natural body' is constituted. Potentiality and quantity result from the material principle; actuality and quality result from the formal principle. Matter and form, therefore, are

present in all bodies, living and nonliving. In elements and compounds the form is inorganic, while in organisms it is vital; matter is the same in inorganic and organic beings.

Since, as Aristotle states, “a thread of wool will not make a saw,” or, in other words, since there is a natural law governing the transformation of bodies, Aristotle postulated a *rhythmic evolution of forms* in substantial changes. A definite finality or purposive-ness pervades and controls the processes in nature. Substantial forms do not, therefore, appear at random in new bodies, but only those which the exigency of matter demands at this particular stage of transition.

Such is the famous hylomorphic theory of Aristotle, devised by him to explain bodily constitution and substantial change.

MEDIEVAL SOLUTIONS

With the exception of *Epicurus* (about 342—270 B.C.), who revived the teachings of Democritus, no noteworthy contributions to the philosophy of physical essences were made until the Middle Ages. In consequence of the downfall of the Roman Empire and the devastations of the migrating nations from the East, the pursuit of philosophy stood at a standstill for centuries. The works of the Greek thinkers became almost unknown.

The Middle Ages witnessed the resurrection of philosophy in the Western World. The first efforts in philosophy were feeble, uncertain, groping. Lacking a traditional system of thought, the pre-scholastic

philosophers during the period from the eighth to the twelfth century borrowed their ideas from fragmentary sources of ancient Greece and propounded theories which were heterogeneous and often contradictory. Platonic ideas were quite prevalent. Aristotle's hylomorphism received little attention and was usually misunderstood. The 'form' was taken in the sense of the 'sum of the properties' in a thing. Some held the 'matter' of Aristotle to be the chaos of elements; others were atomists and maintained that matter is the aggregate of atoms; others again looked upon it as a general mass with a qualitative constitution, possessing dynamic movement. Only a few, men like *Isidore of Seville* (7th century), *Rhaban Maur* (784—856), and *Gilbert de la Porrée* (1076—1154), seem to have grasped in a confused way the fundamental concept of 'matter' as advanced by Aristotle. There were, however, two Arabian commentators on Aristotle, *Avicenna* (980—1037) in the East and *Averróes* (1126—1198) in Spain, who did much to make Aristotle known to the philosophers of the West. Through the untiring efforts of prominent scholastics, such as *Alexander of Hales* (died, 1245), *St. Albert the Great* (1193—1280), *St. Thomas Aquinas* (1224 or 1225—1274), *St. Bonaventure* (1221—1274), *Henry of Ghent* (died 1293), and *John Duns Scotus* (1266 or 1274—1308), Aristotle's theory of matter and form as the constitutive substantial principles of bodily essence was developed more fully and became the dominant cosmological doctrine of this glorious age of philosophic thought. Though these great minds disagreed on some important points, the hylomorphic theory in its main features was common to them all. For this ascendancy

of hylomorphism the brilliant genius of St. Thomas Aquinas was chiefly responsible, so that the theory is often referred to as the 'aristotelian-thomistic theory.'

The fourteenth and fifteenth centuries saw the decadence of scholasticism. The Renaissance and Reformation assisted in bringing it into complete disrepute. Finally, the rise and success of the natural sciences all but obliterated it for a time.

MODERN SOLUTIONS

The great scientific discoveries of *Copernicus* (1473—1543), *Tycho Brahe* (1546—1601), *Kepler* (1571—1631), *Galileo* (1564—1642), *Boyle* (1627—1701), *Newton* (1642—1727), and *Lavoisier* (1743—1794) revolutionized astronomy, physics, and chemistry. Scientific explanations replaced philosophic theories. Soon, however, the scientists also became philosophers, and new theories of the ultimate constitution of bodies began to make their appearance.

René Descartes (1596—1650) brought *atomism* and *mechanism* into vogue. He maintained that the essence of bodies consists in *extension*. Bodies have no real activities of their own; even the bodies of living beings, including man, are nothing more than machines, and there is no soul or animating principle present in them as a *substantial part* of the bodily essence. *Local motion* is the sole cause of all change in the corporeal world, and this motion is extrinsic to the bodies themselves. God produces and sustains all motion; the bodies merely modify it according to their difference in mass and shape. *Gassendi* (1592—1655)

advocated a mechanical atomism more along the lines of the ancient Greeks.

Gottfried W. Leibnitz (1647—1716) opposed Descartes' theory with his doctrine of monads. Bodies consist ultimately of monads, and they are simple, indivisible, unextended substances. No two monads are alike; all are endowed with *life*; and all possess the 'power of representation' or knowledge, some consciously and others unconsciously. Each monad is a universe in miniature, because each one mirrors within itself whatever happens throughout the world. Interaction between single monads is only apparent, not real; the union of monads to form bodies is purely extrinsic. Substantial change is, therefore, impossible. Monadism is *pan-psychism* and a form of *dynamism*.

The views of Descartes and Leibnitz were diametrically opposite. A variety of systems followed in their train, some atomistic, others dynamistic.

Dynamism. The monadism of Leibnitz was eventually developed by a number of philosophers into a system of *dynamism* proper. In the place of simple monadic substances they substituted *forces* as the ultimate constituents of bodies. These forces are *unextended*, but *active*; this is the characteristic feature of dynamism. According to Boscovich (1711—1787), matter consists of such unextended, indivisible force-points, placed at varying distances from one another. 'Action at a distance' is, therefore, a necessary postulate of this theory. These force-points are all homogeneous and are endowed with 'attraction' and 'repulsion.' They interact upon one another;

but this interaction is purely mechanical, being determined solely by the distance between them. These ultimate components are and remain always discrete. The continuity of bodies is only apparent, the result of the impression made on our senses by these unextended forces. This theory, with some modifications, was accepted by Carbonelli, Palmieri, Kant, Him, Leroy, Oerstedt, Gay-Lussac, Cauchy, Faraday, Seguin, Fechner, Lotze, and others.

Atomism. As a reaction against atomism and mechanism, dynamism proved unsuccessful and never had very many followers. On the other hand, *philosophic atomism* soon became the prevalent system in scientific circles. Following the lead of Descartes, scientists restricted themselves more and more to the quantitative, mathematical side of bodies and their processes. *John Dalton* (1766—1844) reintroduced the atom into modern science. According to this scientific atomic theory, the ultimate components of all material substances are atoms or very minute particles of matter. They are extended. The number of the kinds of atoms is comparatively small, and the atoms of the same kind are homogeneous, i.e., are uniform in size, weight, and other properties. Dalton proposed this theory during the years 1803—1807. Daltonian atomism became the basic assumption of all research in the natural sciences and proved to be of great value in their advancement. From scientific atomism to philosophic atomism was but a short step. The latter theory arose from the tendency of scientists to reduce all entities and processes in the universe to the simplest factors. In practice this amounted to the attempt to

reduce all matter to homogeneous atoms and all forces to a single universal force. This tendency resulted in two types of philosophic atomism, the 'mechanical' and the 'dynamic.' The distinction, however, is not always sharply defined.

Mechanical Atomism. This system endeavors to explain the constitution of bodies, their properties, and activities by means of the two concepts of *matter* and *motion*. All bodies are composed of atoms which are essentially *homogeneous*; that is to say, they possess the same kind of essence or nature, and there is only a quantitative, not a qualitative, distinction between them. Chemical affinity, cohesion, heat, electricity, magnetism, light, gravity, etc., are merely modifications of atomic motion; hence, all properties of bodies and all forms of energy can be reduced to *local motion* in varying modes. Atoms are *unchangeable* and *indestructible*. They are also devoid of any principle of activity intrinsic to the atomic substance, because atoms are essentially inert; their activity is due to local motion extrinsically communicated to them. Substantial change, in which one kind of substance would be transformed into another, is, of course, impossible. The processes of nature are the result of the operation of purely mechanical laws and are not controlled in any way by an intrinsic finality of their essence directing them toward definite ends and effects.

Mechanism or, as it is also called, mechanicism is, therefore, an excessively simple system which claims to give an adequate explanation of the universe in all its phases by admitting but two fundamental realities, namely, homogeneous matter and applied local motion. Among the

more prominent scientists whose names are associated with mechanical atomism we find Secchi, Tyndall, Tait, Helmholtz, Berthelot, Clerk-Maxwell, Du Bois-Reymond, W. Thomson, and many others. When mechanism is also applied to organisms, it is termed *materialism*; its chief defenders were Feuerbach, Blichner, Moleschott, and Haeckel.

Dynamic Atomism. Gradually, as the natural sciences progressed and the knowledge of the elements increased, scientists began to realize that mechanical atomism was incapable of explaining all the facts. Local motion could not account for all the phenomena in chemistry and physics. While they accepted the *essential homogeneity of matter* and the substantial *integrity of atoms*, they departed from mechanical atomism by explaining the manifold corporeal phenomena and processes through the agency of *purely mechanical forces*, thereby relegating 'local motion' to a secondary position. However, when it comes to the question of the exact number and nature of these forces, we find considerable divergence of opinion. Some reduce all forces to the fundamental force of *weight*; others, to the force of resistance; others, again, to the two forces of *attraction* and *repulsion*; others, finally, to three kinds of mechanical forces, namely, *attraction* and *repulsion*, *impulsion* by shock or pressure, and inertia. Most scientists have adopted this system as their general philosophy of the world.

Energism. This is a comparatively recent theory, set in opposition to the theory of atomism. Its chief exponent was *W. Ostwald*. He reduced all realities in the universe to *energy*. In physical science energy is defined as the capacity

to do work, and work is the product of a force times the displacement it produces in the direction in which the force acts. This is a mechanical concept of energy and far too narrow in meaning to fit into the theory of energism as conceived by Ostwald and his followers. For them energy is all reality; everything that occurs in the world, occurs through energy and in energy. *Energy is everything and everything is energy.* Bodies are nothing but complexes of energy; there is no substance which is the bearer or subject of energy. Even such *quantitative* factors as volume, extension, weight, and mass are merely forms of energy; they represent energies which usually are designated as 'matter.' Besides these, there are energies which are *intensive* in character, such as heat, electricity, chemical affinity, etc. Vital functions are a form of chemical energy, and rational activities are the manifestations of a 'psychic energy.' 'Things' no longer exist, but only processes, phenomena. Energism is a modernized variant of dynamism.

Electronism and Aetherism. In our own day many physicists incline to the view that matter is *electricity*. They view electrons and protons as electricity pure and simple, not as portions of matter endowed with negative and positive electricity. Witness this statement of Karl K. Darrow: "All matter is electrical; or to put it a little more vividly but not a whit too strongly, all matter is electricity."¹ And Haas says: "In the modern system of physics electricity no longer stands alongside of matter: it has taken the place of matter. The new physics can descry in electricity that unadulterated primordial something for which scientists

sought through thousands of years, and from which all things amenable to sense perception are formed.”² Matter is frequently referred to as an ‘electric wave’ or a ‘condensed electric charge.’ This theory of *electronism* thus seeks the essence of bodies in electrons or electric charges. If electronism interprets the electron as matter-particles, it is atomism; if it interprets the electron as an electric charge pure and simple, it is *dynamism*.

Aetherism, on the other hand, finds the solution of the essence and constitution of bodies in the *aether*. Electrons and protons, which are the ultimate constituents of bodies, are conceived as ‘condensations,’ ‘vortices,’ ‘knots’ of aether. As Sir Oliver Lodge says: “Ether is not electricity any more than it is matter. . . . Over great realms of space there is nothing else; but here and there is a modified portion, so modified as to be the seat and subject of what we call gravity, but exactly how modified we have still to find out. We know the unit of this portion as a localised singularity, capable of position and of locomotion. Can it be a special kind of whirl, or is it a knot or a strain or a bubble, a hollow or an extra condensation, or what? This is the question to be tackled; but as yet we cannot fully answer. In one form we call such individual unit an electron; and we know of such units, and of units akin to them, the atoms of matter are made.”³ At other times Lodge is more affirmative. He speaks of “the apprehensible modification of Ether that we call matter.”⁴ In speaking of the constitution of matter he says: “Electrons and protons are the building stones of which matter is made. The atom of matter is composed of them, and all matter is composed of atoms.

Electrons are evidently composed of Ether, because whatever mass they have is represented by the energy of their electric field, which is certainly an ethereal phenomenon: and apart from this field they seem to have no other existence; they are electric charges and nothing else. We cannot make a similar statement about the proton, because we do not know enough: for that we must wait.”⁵ Other scientists profess similar views. One sees from this that aetherism and electronism are closely related. The advocates of electronism reduce bodies to electric particles and charges; the exponents of aetherism reduce all matter to a form of aether.

Modern Hylomorphism and Hylosystemism. Although the aristotelian-scholastic philosophy, once so powerful in the Middle Ages, had suffered a lamentable decline, it had not disappeared completely. For more than half a century now it has experienced a veritable rebirth in *neo-scholasticism*. The fundamental principles of Aristotle and the schools have been retained without modification. Most of their scientific ideas, however, have been discarded as antiquated and erroneous. Neo-scholasticism accepts the established facts and laws of science and seeks to harmonize them with the principles of Aristotle and St. Thomas Aquinas, convinced that there is no essential conflict between them.

Hylomorphism is still a cardinal doctrine of the new scholasticism. The findings of physics and chemistry, modern scholastics think, are in perfect agreement with their doctrine that the elements and chemical compounds are specifically distinct as *natural bodies*, that *substantial*

changes actually take place in chemical reactions, and that these facts can be adequately explained only under the supposition that all natural bodies are composed of substantial *matter* and *form*. The system will be treated more in detail in subsequent chapters.

Hylosystemism is a recent modification of the traditional theory of hylomorphism. Traditional hylomorphism is applied with equal stringency to inorganic and organic bodies. Hylosystemism distinguishes between these general types of bodies. It admits hylomorphic composition in organic beings, but it denies this composition in the atoms, elements, and chemical compounds. It maintains that these inorganic bodies are nothing more than *dynamic systems* of subatomic particles which act as *functional units*. This system will also be treated more fully in subsequent chapters.

Such, then, are the problems confronting the cosmologist, and such are the solutions offered for these problems. Broadly speaking, the various solutions can be grouped under three main heads: *atomism*, *dynamism*, and *Aviomorphism*. Which is the true solution? It will now be our task to determine which system and theory best interprets the facts and phenomena.

One of the main problems confronting the cosmologist is that of the *essence or essential constitution of bodies*.

SUMMARY OF CHAPTER X

1. *The Question of Substantial Change.* Many scientific facts have been established beyond reasonable doubt; these we accept. The existence of *real change* is too obvious to deny. Are all changes 'accidental,' or are some 'substantial'? The latter is the transition of one kind of substantial entity into a different kind of substantial entity. When atoms combine into chemical compounds or when elements enter into living structures, do they lose their identity as atoms and elements (substantial change), or do they retain their identity and become simply dynamic systems acting as functional units (accidental change)?

2. *The Question of Bodily Essence.* Every *natural body* has an essence or nature which is the ultimate explanation of all that it is, has, and does. Essences are different. Living and non-living bodies are *specifically* different. What is their 'essence'? Are the atoms of the various elements also 'natural bodies,' and are they specifically different?

3. *The Question of Corporeal Constitution.* How is the essence of bodies constituted in its final analysis? Natural bodies have unity of being and operation; yet all are composite beings in some way. What is the *principle of unity* amid all the diversity of parts? There are features in every material substance which are in *apparent contradiction* to each other, such as indivision and divisibility, inertia and motion, quantity and quality. Does this imply a *dualism* of ultimate principles in a body? Then how account for the evident unity of being and operation? Do they consist of

only one substantial principle, matter, with nothing but qualitative differences? Many solutions have been offered.

4. *Earliest Solutions.* The earliest Greek philosophers assumed but a single uniform substance for all bodies. Empedocles introduced four 'roots' or elements. The Atomists were mechanistic and materialistic. Plato found the essence of all bodies in a noumenal world of separated Ideas.

5. *Aristotle's Solution.* Natural bodies have specific essences; they undergo *substantial change*. There are two incomplete substantial principles which constitute the body as a complete substance, namely *matter* and *form*. Matter passes through all changes intact, because it is essentially indeterminate and potential; in substantial change the form is lost and gained, because it is the determining and actualizing principle. This system is called hylomorphism.

6. *Medieval Solutions.* After a number of tentative solutions, the *hylomorphism* of Aristotle and St. Thomas Aquinas became the dominant theory.

7. *Modern Solutions.* Descartes brought atomism and mechanism into vogue: Leibnitz introduced monadism, a form of *dynamism*.

Boscovich developed *dynamism* proper: the ultimate constituents of bodies are unextended but active *forces*. Scientific atomism became *philosophic atomism*. Philosophic atomism appears in two types: mechanical, which explains everything through matter and motion; *dynamic*, which adds the concept of mechanical forces to the concepts of matter and motion.

Energism reduces all reality to energy, without a material substance as its bearer. *Electronism* conceives all matter as electricity; and *aetherism*, as variations of the aether.

Modern hylomorphism seeks to harmonize the facts of science with the hylomorphic system of Aristotle and St. Thomas Aquinas. *Hylosystemism* is a modification of hylomorphism: it admits hylomorphic composition in organic bodies, but maintains that inorganic bodies are hylomeric, i.e., dynamic systems of subatomic particles acting as functional units.

Editorial Thought From: *The Atom in the History of Human Thought*

In light of all these data, it is clear that the fundamental and unconditional distinction Democritus had introduced between atoms and vacuum can no longer stand. Not only has vacuum invaded atoms to the point that it occupies virtually

their entire volume, and not only have atomic and subatomic particles been plunged into a veritable ocean of virtual particles with which they continually interact, but even the most intimate properties of atoms can no longer escape vacuum's dictates. Democritus's vacuum was an inert playground for atoms to frolic on. It has now been supplanted by an active vacuum participating in the making and evolution of the world. For better or worse, it even appears possible that it actually was the primordial source from which the universe sprang to life through "a gigantic original fluctuation," whatever is meant by that phrase. Thanks to quantum randomness and Einstein's equivalence of matter and energy, Democritus's two principles end up merging into a unified concept. To be sure, on closer examination, the two principles retain a certain specificity embodied for instance in the different properties of fermionic and bosonic fields, but, on a fundamental level, these are merely two facets of the same reality.

Chapter 11

DYNAMISM AND ATOMISM

HAVING SPECIFIED THE PROBLEM AND HAVING GIVEN A BRIEF survey of the main systems which have attempted a solution, we must now turn our attention to an examination of these systems to see whether their explanation is rationally satisfactory.

The problem of the *ultimate constitution* of bodies cannot be solved by scientific observation and experimentation. The 'essence' of things escapes sense perception, because the senses perceive only the external phenomena. True knowledge of the essence of things is a matter of *rational inference* from their properties and activities; these flow from the essence as from their root-principle and consequently reveal the essence.

Any system which cannot account completely for all the properties and activities of bodies must be adjudged inadequate or erroneous. This does not mean that there is no truth at all in the system; as a rule, truth and error are mixed. Some systems fail through defect, others through excess. The true system must give a *complete and natural explanation* of all phenomena in question. The data of the experimental sciences must serve as the basis of discussion,

because they represent the factual evidence from which the intellect must infer the essence and constitution of natural bodies.

Dynamism and *atomism* appeal to the intellect because of their extreme simplicity. These, then, shall be examined, together with a few cognate systems of thought.

MONADISM

It is unnecessary to say much about the monadism of Leibnitz. It is a fanciful theory, based completely on gratuitous assumptions which are contrary to experience. All monads are supposed to be endowed with *life* and *knowledge* — an assumption based on no evidence.

This theory contradicts one of the most patent facts of nature, namely, the distinction between living and nonliving bodies. Whatever may be said about atoms and compounds, living bodies are certainly 'natural bodies' with a unity of structure and operation. But monads are the only units recognized by Leibnitz; hence, the *unity of the organism* remains unexplained, because there is no principle in monadism to unite the single monads into an organism.

As for the *knowledge* of monads, in virtue of which each monad mirrors all that happens to other monads throughout the universe, this is fantastic and obviously false. Man's *mind* is a monad. Consciousness, however, testifies only too clearly, that we do not know everything that happens to other monads; we are even ignorant of much that takes place in the vital functions of our own body.

Since the monads are unextended, simple substances, the fact of *extension* in bodies becomes inexplicable. No sum of unextended substances (no matter how great), can ever produce extension, because, what none of them have, their totality cannot have. Extension, however, is one of the most important facts about bodies. Hence, monadism is inadequate.

DYNAMISM PROPER

All dynamistic theories assume that bodies consist either of *pure forces* or of *unextended active substances*. Neither view is adequate as an explanation of the nature of bodies.

Neither view can explain the *extension* of bodies. This was shown in the chapter on quantity and extension (Chapter 6). Dynamists find a contradiction in the very concept of continuous extension. But extension is a fact of physical nature; even dynamists admit that we have the 'experience' of extension. But how is it possible to have an experience of something which does not exist? And if it exists, how can it exist, when the ultimate components of bodies are all unextended? That our own bodies at least are truly extended, is witnessed by the incontrovertible testimony of our *consciousness*. Consequently, the ultimate constituents of our bodies are extended, not unextended. Then dynamism must be wrong.

It is also a contention of dynamism that these unextended force-points or substances are not in contact, but are separated by *space intervals*; they are situated at some *distance* from one another. That implies 'action at a

distance.’ That, however, as was pointed out before, involves a contradiction in terms.

Dynamism destroys the *unity of organisms*. Since these force-points or simple substances are at a distance from one another, they cannot be in contact; and if they came into contact, they would coalesce into a mathematical point, because they have no extension and must coalesce with their whole being in the same point. In that case, however, how can there be anything like the *body* of a plant, animal, or man, with a *differentiated structure of cells*, organs, and tissues? After all, organisms are not mathematical points, but spatially extended structural units. This organic unity amid structural diversity is one of the characteristic features of every organism, and dynamism leaves this an unexplained enigma. Hence dynamism must be rejected.

ENERGISM

Energism, in opposition to mechanical atomism, insists on the presence of ‘qualitative’ factors in the scheme of corporeal processes; this is, of course, correct. It fails, however, in giving a comprehensive explanation of nature by going to the opposite extreme.

In reducing all reality to energy, it cannot account properly for the properties of bodies which are grouped under *quantity* and *extension*. Energy is essentially an ‘active’ agent. Many properties of bodies, however, such as extension in three dimensions, inertia, volume, mass, shape, weight, etc., are essentially ‘passive’ in character. To reduce these properties entirely to energy is an arbitrary

procedure and hardly in accordance with the facts of science.

Most advocates of energism are of the opinion that the concept of a *substance* as the bearer of energy is superfluous and nothing but a mental abstraction. This is a deplorable error. The philosophic concept of 'substance' is indispensable. Realities exist either in themselves without a subject in which to inhere or they exist in something else which is their bearer and which they modify as an accessory entity. In the first case they are 'substances' and in the latter case 'accidents' or modifications. If the various forms of energy do not exist in any kind of underlying support, they exist in and for themselves; then they are 'substances' in the philosophic sense, and it is wrong to deny the existence of substances. If they exist as modifications, they must modify something and this 'something' is then a substance. In any case, 'substances' must exist if energies exist. Then, however, not the energies themselves but the underlying substances are the ultimate realities in bodies.

Energism also rejects the concept of *matter* as a constitutive factor in bodies. This excessive exclusiveness is a defect of the theory. Energy is a 'dynamic' principle which is the source of activity in bodies, and activity is, without doubt, one of the most important features of bodies. It is, however, not the sole feature. Equally important is the inherent 'static' character of *space diffusion* and *mass*. How can such diametrically opposed properties proceed from one principle, and that a principle of activity? Matter, as a principle of passivity and diffusion in bodies, is definitely required as a factor in the constitution of bodies. We agree

that energy is not a 'substance' and not 'matter.' That, however, does not eliminate substance and matter. On the contrary, every body is a 'material substance' or 'substantial matter' endowed with energy in various forms. It is precisely the defect of the theory of energism that it lifts a mere *power of action* into the position of *substance* and *matter* instead of a 'modification' and 'qualification' of substance and matter. Bodies all contain within themselves a stable, permanent reality which remains intact, notwithstanding the constant change and transformation of energies within its being. This reality is termed 'matter' or 'material substance'; its existence is as much a fact as the existence of energy and activity, and it must be accounted for. Energism fails to do this.

Even *vital function* and *rational activity* are reduced to a form of energy in this theory. And thus the *specific difference* between plant, animal, and man, and between organic and inorganic beings, is left unexplained. There is more in organisms than the mere energies of heat, electricity, chemical affinity, mechanical motion, etc. These energies, it is true, are present in organisms, but the vital functions of nutrition, sense perception, and rational thinking are functions so vastly superior to the activities of ordinary energies, that they can be conceived only as proceeding from a totally different kind of *principle*.

Energism is thus seen to be but a variant of dynamism and labors under the same difficulties.

ELECTRONISM

We treat *electronism* here in so far as it is also a dynamistic theory. According to this theory, all reality is reduced to pure electric *charges*. Bodies consist of atoms, and atoms of electrons and protons; these are the ultimate constituents of all bodies. Dynamistic electronism does not consider these constituents as material particles or corpuscles endowed with electric charges of opposite sign (positive and negative), but it identifies them with *electric energy* itself; they are 'condensed electricity,' 'condensed electric charges,' devoid of matter as their bearer and support.

In this sense, electronism is a form of *energism*, and the reasons advanced against energism apply with equal or greater force against electronism. Energism admits the existence of various types of energy and does not attempt to reduce them all to one. Electronism knows only one form of energy, electricity, and must explain all inorganic and organic activities by means of this single energy. However, to explain all the activities of elements, plants, animals, and men as being ultimately nothing more than the action of electric charges, is a hopeless undertaking. Vegetancy, sentiency, and rationality demand a much higher principle of being than that found in an electric charge.

Electronism is based on the confusion of *phenomena* with *substantial reality*. The mere fact that electrons and protons are invariably associated with negative and positive electric phenomena does not warrant the conclusion that these particles are nothing more than pure electricity without a material support as their bearer. On the contrary, the *evidence of science* is against such a view. So far as electric *charge* is concerned, electrons and protons are

alike; both possess unit charges of electricity, equal in magnitude, so that they neutralize each other. But electrons and protons are very unequal in their respective *masses or weights*. The proton is approximately 1845 times as heavy as the electron. Due to its greater weight, the proton does not travel as fast as the electron; nor is it bent out of a straight course in a magnetic field as far as an electron. On the supposition that they are nothing but 'grains' or 'atoms' of pure electricity, this is inexplicable, because, their charge being the same, their electromagnetic mass should also be the same and their velocity in a magnetic field should be the same. Besides, science has proved beyond reasonable doubt that they are true *projectiles* which follow the mechanical laws of impact, as can be seen in the Wilson chamber, and produce mechanical effects, as can be seen in using them for bombarding elements. This shows clearly that they are *particles of matter* endowed with electric charge, not pure electricity itself. Electric energy, therefore, is attached to these material particles as an accessory entity, but does not constitute them. *Matter* is the *bearer of energy*, not energy itself. Hence, electronism cannot give an adequate explanation of the ultimate constitution of bodies.

All types of dynamism fail to explain the passivity, the *extension*, and the materiality of bodies in general and, most of all, the *specific structure* and *vital functions* of organisms in particular. Dynamism, therefore, must be rejected as an inadequate philosophic theory of the constitution of bodies.

MECHANICAL ATOMISM

The philosopher has no quarrel with *scientific atomism*. He admits the existence of 'atoms' as the smallest portions of an element which can enter into chemical combination with another element. He also agrees with the view of modern scientists that the atom is a complex entity, ultimately composed of electrons and protons, etc. The latter, and not the 'atom' in the Daltonian sense, are the ultimate physical constituents of all elements and bodies. So long, then, as physicists and chemists stay within these self-imposed limits of their science and do not claim to explain the *ultimate essence and constitution* of bodies in these terms, the philosopher is in accord with them. *Philosophical atomism*, however, is a metaphysical, not a scientific, theory of natural bodies, and as such it must be evaluated by the philosopher.

In explaining the essence and ultimate constitution of all bodies, mechanical atomism accepts two realities, and two realities only, namely *homogeneous atoms*, and *mechanical, local motion*. Everything in nature is supposed to be explained through these two factors. A theory must actually explain in a rationally satisfactory manner all that it sets out to explain; if it does not, it must be adjudged erroneous. That, we contend, is the case with mechanical atomism, because 'mass' and 'motion' alone cannot account for the most important phenomena observed in nature.

Mechanical atomism maintains that all atoms are *homogeneous*. Science has definitely proved that this is not so. If we take the 'atoms' as the minimal portions of the

various elements retaining the character of these elements, we now know that the elemental atoms are of about *ninety-two different kinds*, with different atomic weights, with different properties and activities, with a marvelous complexity of structure, and with a composition of radically different subatomic particles. Atoms, therefore, are not homogeneous; they are heterogeneous. If we substitute 'electrons' and 'protons' for the older concept of the 'atom,' we again find heterogeneity; they are radically different in mass and possess opposite electric charges.

Again, atoms are supposed to be *inert*, without any inherent principle of activity. The only motion in the world is *local motion* and it is *extrinsic* to the atoms, being communicated to them from without. This assumption has also been disproved by scientific research. The atoms of the *radioactive elements* are extremely active within their own being, independent of other atoms or bodies. No outside activity of other atoms or bodies can retard or hasten the disintegration of the radioactive atoms or modify in any way the release of the tremendous energies locked within the body of such atoms. Alpha and beta particles are ejected with enormous velocities, not through local motion communicated from without, but through the intrinsic activities within the radioactive atoms themselves. The local motion of these particles is *not the cause*, but the *effect*, of the internal disintegration taking place within the active substance of the radioactive elements. There must be, then, a principle of activity inherent in the atom, causing local motion. In other words, atoms are not inert substances; they are endowed with inherent *energies*, making them

capable to a certain extent of self-activity. In our day there is hardly a scientist worthy of the name who does not admit the existence of energy as a necessary factor in physical and chemical processes.

In the *inorganic world*, the atoms of the elements are the fundamental natural units of bodily existence. These atoms can no longer be viewed as simple entities; they are complex units, composed somehow of electrons and protons, etc. Hydrogen has one electron and one proton; uranium has 238 electrons and 238 protons. If mass and motion are the only factors responsible for the formation of these elemental atoms, why does not the addition of one electron and one proton to the number of those contained in the atom of the preceding element give rise to another element, so that there would be 238 elements? There are, however, only about 92 permanent elements. The *atomic weights* are not evenly spaced from one element to the next. Yet these elements possess *typical properties* which enable them to be recognized with ease. Mere mass does not account for these typical differences of the elements; this is proved by the frequent presence of isotopes among them, where the difference of mass does not entail a difference of properties. Neither can mere mass account for the *periodicity* observed in the elements; the mass of the elements increases progressively from hydrogen to uranium, while the properties recur in periodic cycles between one Zero element and the next. According to the tenants of mechanical atomism, there is no rational explanation for the various clearly defined types of atoms which we call 'elements' and for the obvious periodicity of

their properties and activities. There should be nothing but a homogeneous agglomeration of atoms, molecules, and larger bodies, subject solely to orderless local motion. The atoms of elements are 'typical' in the strict sense of the term, and this demands a typical structure in the internal configuration of the electrons and protons. Such a structure, however, manifests law and order, and that requires a principle of law and order intrinsic to the constitution of the atom. In passing from inorganic atoms to inorganic molecules and compounds, we find the clearest evidence of typical structure in *crystals*. The geometrical construction of crystals cannot be the result of homogeneous atoms swirling about in desultory fashion through the action of local motion impressed upon them from without. Crystals *build themselves*. There is, and must be, an *intrinsic principle* of law and order which arranges the atoms and molecules according to a definite plan and design. Mechanism is helpless in the presence of the 'types' found in inorganic nature.

In the *organic world*, the existence of typical structures is a universal feature of all organisms. The very term 'organism' implies the arrangement of various parts and organs into a harmonious whole and unit. How 'typical' these structures are, can be seen from the fact that plants and animals are classified according to *specific types*, and these 'species' run into the hundreds of thousands, each clear and distinct in its characteristic structure. There is nothing haphazard in the configuration of this structure. There are, to be sure, freaks of nature which deviate from the standard type, but they are the exceptions which prove

the universality of the rule. Not only are the structures of organisms distinctively typical in themselves, but they are the result of an *intrinsic principle of growth and development* resident in the very texture of the original germ cell. The bodies of plants, animals, and men are not the outcome of the native tendencies of the component chemical elements. On the contrary, these elements are utilized for the needs and purposes of the organism as a whole. *Organisms develop themselves* according to a definite plan into a unified structural *whole*, the integral parts and organs revealing a marvelous complexity, differentiation, and specialization. There is a purposiveness, an *internal finality*, in the development of each organism, from ovum to full maturity, which is unmistakable and undeniable. The *unity* of the organism is such that every function and every part is under the all-pervasive drive and control of some dominating principle which regulates and co-ordinates everything for the welfare of the organism as a completed unit. Any other interpretation does violence to the facts. Mechanistic atomism has no place in its theory for *purposiveness, finality*; it recognizes no principle of direction and control which could arrange atoms for definite purposes and ends. All is supposed to be explained by homogeneous atoms and indifferent local motion. No thinking mind can accept such a mechanistic interpretation as an adequate explanation of the *law and order* found in organic beings. Mechanism fails as an explanation of inorganic atoms and compounds; it fails doubly as an explanation of organic structures.

If mechanical motion is the sole *principle of activity* in atoms and bodies, then properties and activities can be nothing more than a form of *local motion*. This is an untenable theory. The natural sciences disclose many properties and activities which cannot be explained on so simple a basis. *Electromagnetic fields of force* are not forms of motion; they are states of tension in the aether which are qualitative in character. Such fields of force produce local motion in an electrified body: they are not its effects.

The kinetic theory of gases demands the existence of *elasticity* in the atoms and molecules of a gas; but this elasticity is a qualitative property, not a form of motion itself. *Cohesion* is another property of matter which cannot be described as a form of motion. Cohesion tends to hold the parts of a body together, so as to resist the dissipating force of collision and impact. Electrons, protons, neutrons, alpha particles, and other bodies are, absolutely speaking, quantitatively divisible; yet they resist divisibility to the utmost. Neither the bombarding nor the bombarded particles in artificial disintegration ever succeed in fractioning the ultimate constituents of elements, namely, electrons and protons, notwithstanding the terrific impact to which they are subjected. The cohesive force holding these particles together must, therefore, be far greater than the impact force of particles moving with enormous velocity; cohesion resists motion and dissolution by motion, and as such is a qualitative property of bodies. Even the *attraction* between electrons and protons and the *repulsion* between electrons and electrons and between protons and protons cannot be explained as mere forms of motion; they

are prerequisite qualitative properties which, through their action upon electrified particles, *produce* local motion in them so that these particles are said to be 'attracted' or 'repelled.' Similarly, *chemical affinity* is much more than local motion. This selective tendency of the elements for one another is present in them at all times and is independent of motion. It is a qualitative determination of the elements, not mechanical. Elements will unite into a compound because they are of a characteristic type, not because of any mechanical motion communicated to them. One need but glance at the *activity series* of elements, to realize the truth of this statement. For example, potassium and sodium unite with oxygen with great facility; zinc and copper are oxydized rather slowly; gold and silver do not combine at all under ordinary conditions with oxygen; magnesium will liberate hydrogen very rapidly from dilute acids, while lead does it very slowly. Other elements, such as the inert zero elements, show no tendency to make compounds. In no case are these reactions determined by any mechanical motion to which the atoms may be subjected; on the contrary, the motion and arrangement of the atoms is brought about by such qualitative factors as their 'metallic' or 'acidic' character and by other properties peculiar to the group to which they belong. The claim, therefore, that all so-called qualitative properties' can ultimately be reduced to the quantitative difference of homogeneous atoms and mechanical motion, is fallacious.

Mechanical atomism is an oversimplified system. Many fundamental and universal facts about atoms and their compounds either must be denied for the sake of theory,

and then atomism runs counter to natural science, or these facts are not accounted for in accordance with the principles expressly stipulated by the theory, and then atomism is a failure as a philosophic explanation of the essential constitution of physical bodies. Oversimplification is always a serious danger to any theory which attempts to explain nature as a whole; because nature, far from being simple in structure and operation, is exceedingly complex.

DYNAMIC ATOMISM

As the natural sciences progressed, scientists realized that mechanical, local motion could not be the all-embracing explanation of phenomena. More was needed. Hence, while retaining the tenets of philosophical atomism in its main features, atomistic philosophers sought to correct its deficiencies by introducing the *dynamic* factor of *force*. This, they felt, was sufficient to save the theory from failure.

According to this view, matter is still essentially homogeneous, and atoms remain substantially *unaltered* throughout their existence, whether in the free state or in compounds. There is no such thing as a real 'substantial change' in atoms or bodies; atoms never lose their original substantial identity. Whatever changes take place, are minor and accidental and do not affect the fundamental reality of the atoms. These changes are physical or chemical and are produced through the agency of *purely mechanical forces*. As was mentioned in the foregoing chapter, some dynamic atomists reduce these forces to weight; others, to resistance; others, to attraction and repulsion; others, to

attraction and repulsion, impulsions, and inertia. This theory, though an improvement on pure mechanism, still falls short of being an adequate philosophy of nature.

The explanation of the *function and structure of elemental atoms* on the basis of purely mechanical forces leaves much to be desired. We accept, in this connection, the *nuclear atom* of modern science. It is true that much of our knowledge of the nuclear atom with its planetary electrons is speculative and theoretical, not positively demonstrated in a scientific sense; hence, it is subject to revision and correction. Scientists in general, however, subscribe to the view of the 'nuclear atom' as a fairly accurate description of its structure, and the dynamic atomists are mostly scientists. We are, therefore, justified in using this theory as the premises of our argument.

Now, if the nuclear theory is a substantially correct interpretation of the structure of the elemental atom, dynamic atomism cannot give an adequate explanation of the facts. No explanation can be given for the fact that *all protons* and only *some electrons* form the *nucleus*. Protons, possessing a like electric charge, repel one another. Since there is an excess of protons in the nucleus, why do they not repel one another there? What holds them together? Why are not all protons united with electrons? Why are some electrons in the nucleus and others in planetary orbits? If some electrons can enter the nuclear region, why not all? And if some cannot enter this region, why can others? Why a nucleus at all? Why should not each proton simply attract an electron and, thus neutralized, go off on an independent course of its own? Why the various orbits and energy levels

for the different planetary electrons? Why the specified number of electrons in these orbits and levels? Why do some electrons revolve in orbits around the nucleus and others not? Why should the nuclei range from one proton in hydrogen to 238 protons in uranium? Why does the build-up of nuclei stop at uranium and not continue indefinitely beyond that point? Why are some nuclei unstable, as in the radioactive elements, while others remain stable? Why is the rate and succession of disintegration so different in different radioactive elements, and yet so fixed and unalterable in each element? Why does all radioactivity stop with lead? Why the tendency to form enormous quantities of one element (for example, carbon, oxygen, hydrogen) and very limited quantities of others (for example, gold, platinum, radium)? If *mechanical forces* are the only agencies at work in nature, these and similar questions cannot be answered. Such forces can produce only mechanical motion of a definite velocity and direction, but they cannot account for the complicated structures revealed in the nuclear atoms of the elements.

Dynamic atomism has no intelligent explanation for the various *types of properties* found in elements and chemical compounds. This theory claims that all atoms are homogeneous in their substance. But the substance of a thing is the root principle of all its properties. The same kind of substance, therefore, must have the same kind of properties. In that case, there should be no difference of properties in the elements and their compounds. But this is manifestly not so. Compare one element or compound with another from the standpoint of fusion point and boiling

point, solubility, specific gravity, color, odor, savor, magnetism, and many other properties, and they will be found to vary greatly. If all are composed of homogeneous, substantially identical matter, their properties should also be identical. Whence, then, the difference?

Dynamic atomism can give no account of the difference between inorganic and organic bodies. Both types of bodies consist of the same elements and elementary atoms. But all atoms are supposed to be substantially identical, and the only forces active in these atoms are purely mechanical. Hence, there can be, in this view, no essential difference between inorganic and organic bodies. But this does violence to reason and fact. The difference between them is fundamental and *essential*. In inorganic nature the elementary atom is an individual unit with a particular activity of its own; in the organism it loses its individual unity and becomes an integral, subordinate part of the higher unity of the structural whole. In inorganic nature the elementary atom combines with other atoms strictly according to the exigencies of chemical affinity; in the organism it is forced to make compounds which are greatly at variance with its natural inorganic tendencies. In inorganic nature the elementary atom manifests nothing but 'transient' activity; in the organism it participates in the 'immanent' activity of vital function, so that its activity is elevated to a far superior plane. In inorganic nature the elementary atoms will unite with other atoms in any quantity, provided they are present in the proper proportions, so that, for example, oxygen and hydrogen will unite into a drop or into an ocean of water; in the organism

the quantity of any element or compound is restricted by the needs of the organism as an individual. In inorganic nature the elementary atom and compound has an independent existence and larger bodies are mere aggregates of single atoms and compounds; in the organism the single atoms and compounds are welded into a complex system of cells and organs under the directive control of a unifying, centralizing principle which makes all individual units subserve the common welfare of the organism as a whole. This difference between the same atom and compound in the organic and inorganic state is not superficial but fundamental, not accidental but essential: living and nonliving beings simply belong to an entirely *different order of being*.

Furthermore, it is repugnant to sound reason to maintain that there is only an accidental difference between the three main types of organic *life, plants, animals, and men*. Vegetative life, sentient life, and rational life are so radically diverse in operation, that it is preposterous to group them in the same general class. Now, function reveals essence, because the essence manifests itself in function. But when functions are of an entirely different order, so that one type of function is found exclusively in one type of organism and never found in the other, it is a plain indication that the essences underlying these functions are *substantially distinct*. Only *crass materialists* are bold enough to deny the essential distinction between plants, animals, and men, and between living and nonliving bodies. The distinction is there and must be accounted for by any philosophic theory which claims to be capable of

explaining the essence and constitution of all bodies which comprise the physical universe. Dynamic atomism, with its meager principles of homogeneous atoms and purely mechanical forces, lacks the necessary philosophic equipment to explain the agencies at work in every organic body.

Dynamic atomism denies all *substantial change* in bodies; atoms remain substantially identical at all times and in all circumstances. This, however, as has been seen, is contradicted by indisputable facts. Whether the elements entering into a chemical compound undergo substantial change, is a mooted question. But when *nonliving* elements and compounds become *living substance*, they certainly undergo substantial change, because in that case there is a transition from one kind of substance into another kind of substance; that is what is meant by 'substantial change.' A corpse is, without doubt, essentially different from the same body when living; but then the elements and compounds, as present in the living and dead body, must also be essentially different. Hence, whenever atoms enter into, or pass out of, an organism's *cycle of life*, they must undergo substantial change. And thus it is seen that one of the fundamental tenets of atomism, both mechanical and dynamic, falls to the ground.

Finally, according to dynamic atomism, the only powers in operation in the physical universe are *purely mechanical forces*, such as weight, attraction and repulsion, resistance, impulsion and inertia. In consequence of this condition of the theory, all natural processes are mechanical in character; they are forms of mechanical motion. However,

in what intelligible sense can psychic functions be interpreted in mechanical terms? True, *psychic functions* are accompanied by mechanical processes; but that is by no means the complete picture of psychic functions. The sensation of sight, for example, involves forms of motion in the aether, in the retinal layer, in the optic nerve, and in the brain. Vision, however, is none of these motions. Vision leads to the *perception of things*, and that is something far superior to the mechanical processes which mediate the perceived object to the perceiving mind. The same applies to all types of perceptive activities: they are forms of *knowledge*, and knowledge is nothing mechanical. Again, consider the *emotional, intellectual, and volitional states* — pleasure, pain, love, hatred, grief, joy, judgment, rational inference, desire, abhorrence, anger, complaisance, admiration, ambition, and the host of other acts which fill the psychic life of man. These cannot be explained by the agencies of mechanical forces and mechanical motion. Powers and faculties of a nature higher than those of mechanical forces are required as the causes of such processes and states. Mental life is beyond the competence of any kind of physical, chemical, or mechanical force. A *new principle* must be introduced in bodies in order to account for such activities. We call this principle the soul.

Inasmuch as dynamic atomism admits the existence of ‘force’ as a causal agent for mechanical motion, it is an improvement on pure or mechanical atomism. Neither system, however, fulfills the purpose for which it is intended, namely, an adequate philosophic explanation of the essence and constitution of bodies. They fail, because

they are restricted too much to the mechanical inorganic side of the universe and overlook almost completely the fact that organisms are also bodies which must be adequately explained according to the principle of the theory.

AETHERISM

The *aetherism* of some modern scientists deserves no more than a passing comment. To state that all ponderable matter is ultimately reducible to aether, is no answer to the problem of the essence and constitution of bodies. Aether itself is a *body* and needs explaining. The problem is now pushed back into the aether, but it is not solved thereby. What is the essence and constitution of aether? Science knows too little about the aether to venture an intelligent answer. The theory has its points of merit, but it rests more on pure assumption and guesswork than on plausible fact. In its present stage of development, science finds great difficulty in even proving the existence of aether in the universe. The theory, therefore, is based on very flimsy grounds. And even if it were eventually proved that all ponderable matter is ultimately derived from imponderable aether, that would not argue the presence of inorganic and organic bodies, as we know and observe them, out of existence. Ponderable bodies would still remain in the visible universe, and the problem of their essence and constitution would remain with them. Hence aetherism is no adequate solution.

HYLOZOISM

Hylozoism is the philosophic system which maintains that all matter (Gr. *ύλη*, matter) is endowed with life (Gr. *ζωός*, living). It was prevalent among the earliest Greek philosophers and is defended by some modern philosophers. This theory obliterates the essential distinction between living and non-living bodies. A complete vindication of this distinction has not been attempted here, because that belongs to the department of psychology; however, enough has been said to show that the essential distinction between living and nonliving bodies is a natural fact. That being the case, the hylozoistic identification of inorganic and organic matter is unjustifiable and contrary to sound reason. That condemns it as a philosophical system of nature.

In general we may say: The *dynamic* systems uphold the 'qualitative' features of bodies, but neglect the 'quantitative,' material features; the *atomistic* systems stress the 'quantitative,' material features of bodies, but fail to do justice to the 'qualitative' features. Bodies are unitary beings which are neither exclusively quantitative and material nor qualitative and dynamic; they are both, and both aspects of bodies must be adequately accounted for. Philosophical dynamism and atomism err through oversimplicity, the one by excess, the other by defect. The true philosophy of nature must combine the good points of each and thus give an adequate explanation of bodily constitution as a whole.

SUMMARY OF CHAPTER XI

In this chapter dynamism, atomism and a few cognate systems of thought are examined.

1. *Monadism*. It is based on gratuitous assumptions; it cannot account for the unity of organisms; the supposed knowledge of all monads is not a fact; extension in bodies is inexplicable.

2. *Dynamism Proper*. It cannot explain the extension of bodies. It involves 'action at a distance.' It destroys the unity of organisms and leaves the differentiated structures of organisms unexplained.

3. *Energism*. It cannot explain the 'passive' properties grouped under quantity and extension. It errs, when it denies the existence of 'substance.' In rejecting 'matter,' it cannot account for space diffusion and mass. It obliterates the specific distinction between plant, animal, and man, and between inorganic and organic being.

4. *Electronism*. As a dynamistic system, it is a form of energism. It cannot give an adequate explanation of the activities of organic life. It confuses phenomena with substantial reality. It cannot account for the difference in mass between electrons and protons or for the fact that these particles are real projectiles.

5. *Mechanical Atomism*. 'Atoms' as elementary minimal units are not homogeneous. The substance of atoms is *not inert*, as can be seen in the radioactive elements. Since mechanical atomism recognizes *no principle of law and order*, it cannot account for the typical structures observed

in the specific types of organisms; these structures reveal *finality* and demand an intrinsic principle of law and order in natural bodies. Mechanical *motion* cannot explain *the electromagnetic fields of force, elasticity, cohesion, attraction and repulsion, and chemical affinity*.

6. *Dynamic Atomism*. It leaves unexplained the *function and structure of the nuclear atom*; the *types of properties* found in elements and compounds. It cannot explain the *essential difference* between *inorganic* and organic beings, *substantial change*, and *psychic functions*.

7. *Aetherism*. It does not solve the problem of the constitution of bodies, because aether is also a body. It is based on grounds which are too problematical and speculative.

8. *Hylozoism*. It obliterates the essential distinction between living and nonliving beings and as such denies one of the most important features of bodies.

Chapter 12

HYLOMORPHISM

HYLOMORPHISM IS THE THEORY WHICH EXPLAINS THE constitution of 'natural bodies' by means of the *dualistic composition of matter and form*. The theory was devised by Aristotle and subsequently adopted and developed by the scholastics of medieval and modern times. The fundamental tenets of the theory are these: All natural bodies are composed of two incomplete substantial principles; one is the general principle common to all natural bodies, indeterminate but determinable, called *matter*, while the other is the specifying principle distinctive of each type of natural body, actualizing and determining the matter, called the *form*; the union of both principles gives rise to the 'natural body' as a *unitary composite substance*. These few ideas will suffice for the present as an approach to the proper understanding of the theory; a deeper understanding will follow as the theory is evolved in its details.

The primitive chemistry, physics, and astronomy of the ancient and medieval philosophers naturally contained many opinions which were erroneous. Neo-scholastics, in accord with the findings of modern science, have discarded

these antiquated views. They see nothing in science, however, which contradicts the fundamental tenets of hylomorphism. The basic ideas, they contend, are still valid. Some of the more outstanding facts and arguments in support of the theory will now be given.

THE PASSIVE, MATERIAL PRINCIPLE

The universe consists of a *multiplicity* of discrete bodies, not of a single, universal substance. Any being which is the complete subject of activity, exists for itself and is, therefore, a 'substance.' We are certain that many beings in the world are such complete subjects of activity. In our own case, as human organisms, this is perfectly clear. Through self-consciousness, each of us is aware of the indubitable fact that he is the subject, and the *sole subject*, of the activity and changes which occur in his being; none of us refers these activities and changes to any other being outside himself, human or otherwise. Each human being can test this truth for himself. Hence, human organisms are *individual substances* and discrete bodies. Through external observation, we observe a perfect parallel between our own bodies and activities and the bodies and activities of animals and plants; hence, they, too, must be discrete bodies. Inorganic beings are oftentimes 'aggregates,' but in their ultimate constituents (atoms, electrons, protons, etc.) they also reveal themselves as complete subjects of activity; consequently we must assert that they also are individual substances and discrete bodies. The universe, therefore, consists of a multiplicity of discrete substances or bodies.

These discrete bodies do not consist of ultimately indivisible and unextended substantial parts or force-points. This was brought out in our discussion of quantitative extension and in our examination of dynamism. The *activity* of bodies is *diffused in space*. Action at a distance being impossible, bodies can act upon one another only through immediate or mediate contact; but only extended beings have the necessary 'surface' to contact one another, and it follows that only 'surfaced' or 'extended' beings can have an activity which is diffused in space. Since activity is of the same character as the being from which it proceeds (*agere sequitur esse*), it is obvious that the activity of a body cannot be diffused in space, unless the being or substance of the body is also diffused in space. The substance of bodies, therefore, is entitatively *diffused in space*.

Man has a direct proof of this fact in his own body. We are not only conscious of activity in our body, but also conscious of the extension or side-by-sideness of the parts of our body in its activity. Through the experience of double contact, when our hand moves over different portions of our body, we perceive its *diffusion in space* and can measure this diffusion or extension in the three dimensions of length, width, and depth. By the same method, we also perceive and experience the extension of other bodies with which we come in contact. This extension, however, is not merely a 'perception'; it is an *objective feature* of our own body and of other bodies. Hence, all bodies are *entitatively extended*.

Extension, or diffusion in space, is not, however, an activity. The activities of bodies come and go, and there are

many kinds of activities which successively affect bodies, while the extension of bodies remains the same. If, then, we leave the activities of bodies out of consideration and focus our attention solely on the extension of bodies, we find that this extension of bodies consists in their 'being-diffused-in-space' and 'being-spread-out-in-three-dimensions.' This is a *universal feature of all bodies*, no matter what their type of being or activity. And it is a *static, passive* determination of all bodies, because it is nothing active in the sense of 'doing something.' That this is an 'entitative' determination, is clear, because it is the very being or entity of bodies which is thus diffused or extended in space. Such an entitative determination, however, demands an *entitative principle* in the very essence and substance of bodies, in order to account for its presence and existence. It follows, then, that in all bodies without exception there is a *static, passive, entitative principle* which is the foundation and source of the universal determination of extension present in every body. And since that is 'material' which occupies space, this static, passive principle is a *material principle*. We also call it simply *matter*.

All this is in agreement with the findings of science. Bodies are 'acted on' by various forces; they are, therefore, 'passive' and 'potential' to a great extent. Bodies are endowed with 'inertia,' in virtue of which they are indifferent to rest and motion; inertia is also a form of passivity and potentiality. Bodies have 'extensions in three dimensions which can be measured by rule and compass; that, too, is a static, passive factor in bodies. The concept of 'matter' in bodies is common to all the sciences. The

material character of bodies is taken for granted by the natural sciences; there is no dispute on this score. The existence of a 'material principle' in bodies is, therefore, common to science and to hylomorphism.

THE ACTIVE, FORMAL PRINCIPLE

Besides this static, passive, material principle in bodies, there must exist in them also a *dynamic active, formal principle*. This is proved from a number of facts.

For one thing, all bodies are *extended* and *active*. Now, extension of itself does not imply activity. Extension gives to a body merely the side-by-sideness of its internal parts; it diffuses a body in space, so that it occupies space in three dimensions. This, however, is a 'static' and 'passive' determination of bodies and as such does not enable them to be active and do something.

Nor does activity as such imply extension. There are beings which are principles of activity, yet are not extended or material; God, for example, is such a being, and so are spiritual substances. Hence, it seems fairly obvious that the activities of bodies must proceed in them from a principle which is active and dynamic, and this active principle must be entitatively different from the passive principle of extension. This active principle is called the *formal principle* or simply the *form*. It should be carefully noted that 'form,' in the sense used here, does not mean anything like 'shape' or 'figure'; the latter terms pertain to an accidental modification of bodies as regards their external quantity, while the 'form' here means the essential and substantial

principle of bodies which is the source of their activities and properties.

Furthermore, the *specific difference* among bodies proves conclusively that a *formal* principle, distinct from that of matter, is required. While discussing atomism, we have repeatedly referred to the fact that many bodies represent a *real type*, a distinct *species*. This is noticeably true in plants, animals, and man. Each is an individual unit with specific properties and activities restricted to the type to which it belongs. Plants are characterized mainly by metabolic and reproductive functions, animals by sensory functions, and man by intellectual functions. Structurally, they differ in a radical manner from one another. All without exception consist of the *common elements* found in nature. These elements, however, no longer behave in the organisms as they do in the inorganic state. They lose their distinctive individuality, both as regards their properties and activities, and are forced to combine into compounds alien to their native tendencies. They form vital protoplasmic material, cells, tissues, and organs, and thus are elevated into a new state of being with immanent, vital function. An entirely *new principle of activity and corporate unity* is evident in organisms.

This principle is far *superior* to anything found in inorganic beings and cannot have its source in the native, inherent forces of the chemical atoms and elements. Elements and compounds are controlled solely by the laws of affinity and arrange themselves into aggregates of *indifferent amounts*, depending on nothing but the quantity and proportion of the materials at hand. Quartz and

limestone, for example, are formed in layers of any thickness and may cover a continent. Not so in organisms. The amount and type of elements are strictly limited, no matter how large the quantity present at the disposal of the organism. The use of these materials is not determined by the elements, but by the *exigencies of the organism* as a unit; the selection is made according to some purpose inherent in the organism and by a *principle characteristic of the species* of which the individual organism is a specimen. This principle cannot be anything merely 'accidental' to the elements found in the organism. If it were, the elements would not be controlled by this principle, but the principle by the elements; since the elements are indifferent to the quantitative aggregates which they form, the *specific type* so characteristic of every plant, animal, and of man could never originate. A plant derives its origin from a plant, an animal from an animal, and man from man; nowhere in inorganic nature do we observe that organisms originate directly through the compounding of inorganic elements. Hence, the *vital principle* responsible for the origin and development of organisms must be a *substantial* and *essential principle* entirely distinct from any principle present in the chemical elements as such.

The *unity* and *solidarity* of an organism forces itself irresistibly on our attention. In *plants* the activities of the various elements are subordinated in every way to the processes of nutrition, metabolic change, growth, adaptation, and reproduction of the individual plant, and these vegetative functions, notwithstanding their diversity,

all conspire to the well-being of the plant as a whole. In *animals* both the activities of the elements and the vegetative functions are subordinated to the higher functions of sensory life, namely, sight, hearing, taste, smell, touch, central sense, imagination, memory, instinct, emotional states, etc.; and these diverse sensory functions, on their part, are again all directed toward the one goal of the conservation and reproduction of the individual animal. In *man*, finally, all chemical, vegetative, and sensory processes are harmonized in the service of the higher functions of intellection and volition. This unity and solidarity is the result of an *intrinsic purposiveness* or *finality* which dominates the individual plant, animal, and man completely from the first moment of life until death. Since it is not within the natural scope of the powers of the inorganic elements to strive for the purposes which so evidently dominate organic beings, the conclusion is inevitable that the *principle of life* which maintains and develops the organism is *essentially and substantially* different from any principle active in inorganic elements. This means that organisms possess a *specific constitution* composed essentially of matter and a vital principle. In common parlance this principle is called the 'soul'; in hylomorphism it is called the 'form.' Matter and form, therefore, are the constitutive principles which account for the materiality common to all bodies and the specific difference between living and non-living bodies.

Most hylomorphists also defend the hylomorphic composition of *elemental atoms and chemical compounds*. They maintain that the elements are characterized by

specific properties and activities, so that each element represents a distinct type of inorganic body. The *nuclear* atom, as envisioned by modern science, bears out this view in many respects. The planetary orbits, with their definite number of electrons, the energy levels, the classification of elements according to series and groups, the periodicity of properties, in short, the remarkable unity and harmonious arrangement of the structure and activity of each element seems to point to a controlling *inherent principle* working according to a distinct *plan* and for a distinct *purpose*. This, they claim, demands a special constitution, consisting of matter and a formal principle. The same line of reasoning is applied to chemical compounds, for they reveal themselves as specific types of bodies, with properties and activities radically different from those of their component elements. If this is the correct interpretation of the facts, then all material bodies, whether organic or inorganic, are hylomorphically constituted. Other scholastics feel that this argument for the hylomorphic constitution of all inorganic bodies is not cogent; since all elements and compounds consist of electrons and protons, and since these latter seem to retain their essential identity in the elements and compounds, it might be that the difference between the various elements and between the types of compounds is not an 'essential' difference in the strict sense. On the other hand, most scholastics are willing to admit that at least the *electrons* and *protons*, being so radically different in properties and activities, are essentially different and consist ultimately of a material and formal principle.

This much, though, is certain: All specific types of *organisms*, of plants, animals, and man, have a hylomorphic composition; they consist of a static, passive principle (matter) and of a dynamic, formal principle (the form, the 'soul') as the two essential factors in their constitution.

REAL DISTINCTION OF PRINCIPLES

Natural bodies, at least organic bodies, consist of two principles, one material (matter) and one formal (form). Are we to consider these two principles as merely two aspects of one and the same fundamental reality, so that they are logically distinct but identical in entity? Or are we to consider them as two realities, really distinct in their entity? So far as organic bodies are concerned, all hylomorphists agree that there is a *real distinction between matter and form*, so that they are entitatively two different things. They base their contention on the fact of 'unity' in organic bodies and on the fact of 'substantial change.'

It is from the unity of natural bodies, as we have just seen, that hylomorphists draw the conclusion that bodies consist of matter and form. And it is in this same *unity of natural bodies* that they find conclusive proof that matter and form are really distinct as entities in the physical order. This is a most important point in hylomorphism and deserves careful consideration.

The *unity of organisms* is a patent fact. From the standpoint of their material components, however, they consist of a multiplicity of parts. Every single plant, animal, and man is composed of many billions of elemental atoms,

electrons, and protons, etc. Left to themselves, each is an independent unit in its own right. If the unity of an organism were to be derived solely from these component parts, there would be no unity at all in an organism. In most plants we find cells, roots, stem or trunk, branches, leaves, spores or seeds; these are distinct parts with specialized functions. In animals we notice separate cells structuralized into manifold tissues and organs, designed for various kinds of vegetative and sensory functions. This also holds true of the human body. Now, *diversity and multiplicity* are the very opposites of unity. Nonetheless, every plant, animal, and man is characterized by *unity of essence*; they are 'one' thing, not 'many' things. This unity of essence in organisms obviously cannot be derived from the diversity and multiplicity of its material components and parts. Yet the unity of essence is there and must be accounted for. It is the formal principle, the principle of life, of course, which is the principle of this unity of essence. The vital principle pervades the whole organism from end to end, even down to the single cells and atoms, vitalizes and animates them, controls and directs their functions, builds and structuralizes them from a single cell into a most amazing complexity of tissues and organs, and co-ordinates all parts and functions into the supreme unity of *one, single essence*. If the material and formal principles (matter and form) were only logically, and not really, distinct in their being, then, so far as their entity is concerned, the matter would have to be reduced to the form, or the form to the matter. No one doubts that *matter is real* in organisms. Hence, if the form were not really distinct from the matter, there

would be diversity and multiplicity, but *no unity*. But the unity of essence is a fact which cannot be denied; the essential unity of organisms is as real as the diversity and multiplicity of its material parts. Consequently, if matter is real, the form must also be real. And from this it follows that the very nature of an organism as an essential unit composed of a diversity and multiplicity of parts is such, that both matter and form are *really distinct in their entity*: they are not one, but two, entities.

To view this 'unity of essence' from a different angle, consider the *act of sensory perception*. Action reveals entity; hence, as the action, so the entity. In order that an animal actually 'perceive' something, certain organs of perception are necessary. These are structures consisting of many corporeal parts, and they must be connected by means of nerves to the central organ of the brain. The various organs, namely, the eye, the ear, etc., have specific functions leading to definite types of sensation. Here again, viewing the various organs from the standpoint of their materiality, we meet a diversity and multiplicity of parts and functions. Yet the *act of perception is essentially one*. Thus, in the sensation of sight, the light makes a pattern on the retina, and this pattern is spread over many thousands of nerve filaments and over millions of atoms; a nerve tremor is set in motion which travels along the optic nerve to the visual center of the brain, and in this process innumerable cells become active. However, the act of *perception* is not such that one particle sees a fraction of the image and another particle another fraction, so that the final result would be a mosaic of separate perceptive acts; on the

contrary, notwithstanding the diversity and multiplicity of the material parts involved in the process of sensation, the perceptive act is a *unitary act* giving a *single perception* of the object as a *whole*. This is true, not only of the perception negotiated by a single organ, but of all the perceptions of all the organs as a *sensory system*: the organism acts as a unit, an individual of *essential* solidarity, so that the same single individual has the manifold perceptions of sight, hearing, taste, smell, touch, etc. This unity of perception cannot be accounted for in the animal body, if the vital principle or form is not entitatively distinct from the matter, because in that case the diverse and multiple material parts would be the only reality present, and the unity of the organism in its perceptive acts would be destroyed. The form, therefore, must be really distinct from the matter, because it is the *sole principle of unity* in the organism for perceptive acts.

The second main argument for the real distinction between matter and form is based on the fact of *substantial change* in natural bodies. Inorganic bodies have 'transient' action; organic bodies, 'immanent' action. The actions are essentially different; and, since the type of action reveals the type of substance of which the action is the natural expression, inorganic and organic substances are essentially different. If, then, nonliving, inorganic substance becomes living, or if living, organic substance becomes nonliving, this involves a 'substantial change.' And that is what happens. Consider the *fact of nutrition* in plants, animals, and in man. Every living organism is a *single individual*, a single substance and essence. The chemical

elements are the material components of the organic substance, while the vital principle or soul is the formal component. Organisms nourish and develop themselves by selecting certain chemical elements and compounds, rearranging them into organic compounds, assimilating them through the process of digestion, and finally incorporating them as *integral parts* of protoplasm and tissue, cell and organ; they are now animated, vitalized, *living*, and they now participate integrally in the immanent action of specific *vital functions* of which they were totally incapable in their previous chemical state. Furthermore, in the process of vital functioning the organic compounds are broken down, energy is released, and the used elements are eliminated from the organic system; these elements have now ceased to be living and revert to their former nonliving, inorganic condition. We thus see that nonliving elements become living when they enter the organism, and again become non-living when they leave the organism. But while *substantial change* takes place in the elements, the *organism* as such remains *essentially the same*; this is due to the fact that the formal principle (form, soul) has remained intact in the process and has undergone no change in itself. However, if the material principle (the matter) undergoes a substantial change, while at the same time the formal principle (form, soul) does not undergo a substantial change, then it is evident that matter and form are not entitatively identical, but *really distinct*.

This follows also from the *generation and death* of the organisms. Two things are really distinct, when they can be separated from each other. Each of us human beings, for

example, knows that we were not always in existence, but that we began to exist not so very long ago. We have no consciousness of having existed forever in the past, nor of having had previous existence in any other body; hence, we must conclude that our existence as human beings had a definite beginning not so many years back. This consciousness, however, belongs to the formal principle of our being, to our *form* or *soul*. On the other hand, we know that the elements, which belong to the material side of our being, have been in existence in the universe for an indefinite period in the past, long before our own being as a human organism came into existence. Similarly, we know that death will put an end to our existence as a human organism. When death overtakes us, the elements do not leave the body; they remain in the corpse. What leaves the body is the *form* or *soul*. Consequently, it is the form which comes into existence at generation and leaves at death, while the elements existed before generation and remain in existence after death. Death, of course, produces a substantial change in our organism, because the corpse is substantially different from the living body. Since, then, the material and formal principles in man's body can be separated from each other, they must be *really distinct in their entity*. And this is true also of every other type of organism, whether plant or animal. What originates in generation and disappears in death is the formal principle, not the material elements. Hence, in every organism the form must be really distinct from the matter, because the one is separable from the other, and death actually separates them.

Most hylomorphists contend that a parallel exists between organic natural bodies and *inorganic natural bodies*. The natural inorganic bodies are the elements and chemical compounds. They also reveal the presence of a material principle of passivity and indetermination and of a formal principle of activity and determination. When elements combine into a chemical compound, a chemically *new substance* originates through the process of a *real substantial change*; this is proved by the radically different properties found in the compound. This is clear from a comparison of the properties of the compound and of the elements which enter into the compound. Compare, for example, iron oxide with iron and oxygen, or hydrochloric acid with hydrogen and chlorine, water with hydrogen and oxygen, iron sulphide with iron and sulphur, sodium chloride with sodium and chlorine, and so forth.

Chemical compounds, in a sense, manifest properties as specific and typical as those of the organic compounds found in organisms, and the change affecting the original elements is so profound that there seems to be no solid reason why it should not be considered a *substantial change*. Here again, though, the matter of the elements passes over into the compound without loss; the new entity, therefore, which distinguishes the compound from the elements, must be ascribed to the *new form* of the compound as a *single essence*. Hence, even in inorganic bodies matter and form should be considered as *really distinct in entity*. Due to the parallel between organisms and chemical compounds, this argument, without doubt, carries great probability. There is, however, a *formidable*

objection against this view. When elements enter into a chemical compound, a change certainly occurs. The difficult question here to decide is: Is this change really *substantial*? When shall we adjudge a change to be 'substantial' and when merely profoundly 'accidental'? We have no criterion to guide our judgment except the change in properties and activities; they alone give us a clue to the underlying substance and essence. We know that living activities, being 'immanent,' are essentially different from the 'transient' activities of inorganic bodies; hence, the change of elements from 'nonliving' to 'living' is a substantial change. But in the case of chemical compounds the change takes place on a purely chemical, inorganic, nonliving plane. This being so, it is far more difficult to pass a judgment on the nature of the change which occurs when elements unite into compounds. Most hylomorphists are convinced that the difference of properties in the elements and the compounds clearly indicates a 'substantial' change. Recent trends in hylomorphic philosophy incline more to the view that such changes are not demonstrated to be truly 'substantial' and are perhaps only profoundly 'accidental'; they are not so sure that the inorganic form is really distinct from the matter, and some deny the real distinction between them.

We may say, therefore, that in all organisms the distinction between the material and formal principles (matter and form) is real, so that they are entitatively two distinct realities; as regards the real distinction between these principles in inorganic bodies, there is no complete unanimity of doctrine.

SUBSTANTIALITY OF PRINCIPLES

We have shown that, so far at least as organisms are concerned, natural bodies have a hylomorphic composition, and matter and form are entitatively distinct as things. We must now seek to determine whether these two principles are *substantial* or *accidental* principles and, if substantial, whether they are complete or incomplete substances.

A 'substance,' as has been mentioned before, is a being which exists in itself and needs no other subject in which to inhere in order to exist; an 'accident' is a being which cannot exist in itself, but needs another being (substance) as a subject in which to inhere in order to exist. For example, gold is a substance, but its shape or color is an accident inherent in the gold; a dog is a substance, but its act of running is an accident inherent in the dog; man is a substance, but his thinking is an accident inherent in man. An accident is essentially a modification of a substance; as such, it cannot exist independent of the substance which it modifies. All *properties, powers, forces, energies, and activities* are accidents in this technical, philosophical sense, because they are modifications of the substance of bodies and cannot exist except as such modifications.

The question, then, arises: Are matter and form, the material and formal principle in bodies, 'substantial' or 'accidental'? Do they partake of the character of a substance or of an accident? The substance is the *ultimate irreducible reality* in any being, the root and source of everything it is, has, and does. Anything, therefore, that is a reality which is ultimate and irreducible in a body, is

substantial and not accidental. Both matter and form, we claim, are ultimate and irreducible factors in the constitutional composition of natural bodies and as such are 'substantial.'

Take *matter*. That matter is something substantial in all bodies, no one doubts except the thorough-going dynamist who believes in nothing but forces. If matter is not substantial in bodies, what is? For the great majority of scientists and philosophers matter is the ultimate and irreducible reality in all bodies; and for most scientists there is no other ultimate reality in the universe. Matter is the substantial base for quantity and extension and the bearer of energy, force, local motion, and for every activity which occurs in the three dimensions of space. There is nothing beyond matter, of which matter would be a modification in the sense of an accidental determination. Hence, the matter of bodies is *substantial*.

Is the *form* substantial? The forms or souls of organisms certainly must be. We have already proved that vital function cannot have its origin in matter, because the diversity and multiplicity of the material particles constituting the organism cannot give rise to the essential unity of vital function and to the individuality of the living body; the root-cause of life lies in the form or soul. We have also proved that in organisms matter and form (soul) are two really and entitatively distinct realities; they are irreducible to each other. Just as matter is the ultimate and irreducible reality for the material features of organisms, so the form (soul) is the ultimate and irreducible reality for the living features of organisms. But life is the essential

characteristic of organisms. Hence, if matter is substantial, the form or soul of organisms must also be substantial. It follows, then, *that both matter and form are substantial* and not accidental.

The substantiality of matter and form, however, immediately involves us in difficulties. If both are 'substantial' principles, the conclusion seems inevitable that both are substances. But if both are substances, does not every organism consist of two substances? And if every organism consists of *two substances*, we have a dualism of substance, and then what becomes of the *essential unity* of the organism? Does this not bring a contradiction into the very nature of the organism? How can two be one, or one be two?

The *essential unity* of the organism is beyond reasonable dispute. Every plant, animal, and man is an individual, a unit of vital action. Since the substance is the ultimate and irreducible reality of any body, and since the ultimate and irreducible reality in organisms is a single, unitary principle of activity, it is obvious that the organism is a *single, unitary substance*. The organism, therefore, cannot be two substances, but only one substance.

The *duality of substantial principles* in organisms, i.e., matter and form, is an equally clear fact. The matter accounts for the diversity and multiplicity of the corporeal parts in the organic body, but it cannot account for the essential unity of its structure and vital function. The form accounts for the essential unity of the organism's structure and vital function, but it cannot account for the diversity and multiplicity of its corporeal parts. Both matter and form

are required for an adequate explanation of the organism's being. Both are, as just shown, ultimate and irreducible realities in their own line of being in the organism. Consequently, *both must be substantial principles*. And yet, they cannot be two 'substances' in the sense that the organism itself is a 'substance,' otherwise the organism would be two substances and a single, unitary substance at the same time; that would be a contradiction in terms, and such a being would be impossible. How resolve this apparent antinomy?

To resolve this antinomy, hylomorphists distinguish between *complete and incomplete substances*. A 'complete' substance is one which exists in such a manner that its nature demands no further union with a substantial co-principle. Such a substance possesses everything that its constitution and essence require for its existence and for the proper functioning of its natural activities. An 'incomplete' substance is one whose nature demands that it be conjoined with some other substantial co-principle, so as to constitute a complete substance. Each substantial part or principle, taken alone, would be insufficient to exist, or, at least, would be insufficient for all the functions of an individual of that particular species. Thus, man's soul alone, without matter, could not perform the functions of vegetancy and sentiency (for example, digestion and sight), which functions are natural operations for man; man needs matter for them. Neither could the matter alone in man, without the soul, perform the functions of thinking and willing; man needs an intellectual soul for them. Hence matter and form, or 'body' and 'soul' in ordinary language,

are incomplete substances,' each considered alone and for itself; they are substantial parts or co-principles which must be united into a single whole, in order to make a *compound nature* capable of all the functions proper to it. What has been said here of man's nature, also applies to the plant and animal organisms; they, too, are unitary substances consisting of the two substantial principles, matter and form.

While, then, it is true that matter and form are substantial principles, they are not 'complete' substances. They are indeed *substantial co-principles*, but they are *incomplete substances*. Each needs the other to such an extent that each alone is insufficient to constitute the complete organism; it is only in their union as part-substances that the complete and unitary substance of the organism originates, exists, and has its being. And so the antinomy is solved by the fact that matter and form are 'incomplete substances.'

THE COMPOSITE SUBSTANCE

All complete substances are either *simple* or *composite* in their nature. They are 'simple,' when they do not consist of entitatively distinct substantial parts. These are pure spirits; for example, angels or God. A 'composite' complete substance is one consisting of incomplete substantial parts, entitatively distinct among themselves, in such a manner that their union results in a single, *unitary nature*. In a composite substance neither of the incomplete part-substances inheres in the other as in a subject of inhesion;

they complement each other, making a single subject of natural functions through their union. The result of this union is a *substantial unit* (*un urn per se*), not an accidental unit (*unum per accidens*). A thing is said to be an 'accidental unit,' when it consists of two or more complete substances made to collaborate in a unified combination and action, while each component retains its independent substantial entity in the arrangement of the whole. That natural bodies are *composite complete substances* should be obvious. The facts are clear enough and need little elucidation.

A *plant* is a unitary, complete substance. It is not an aggregate of two or more substances forming an accidental unit, but one nature, one substance, a complete individual; for every plant has a unified action, inasmuch as all the parts are present really only as parts, each of which is active in dependence on, and for the benefit of, the whole. Where there is unified action of the whole as a whole, there is also a unified substance, a *single* substance, as the ultimate bearer of this unified action. Thus, the action of nutrition, growth, adaptation, and reproduction in a plant is its own internal action and is essentially one, having as its bearer neither the matter nor the form alone, but the whole plant as a unit. Hence, matter and form in it are united into a single, complete, *composite* substance.

As the plant, so also the *animal* is a unitary, complete substance. Sensation is an immanent action, and as such it must remain in the substance which elicits it. Sense perception, being a material and extended act, demands matter; but, being a living and immanent act, it also

demands the form or soul. If both matter and form were complete substances, each would have its own act, and there could be no unitary act. Hence, it is neither the matter alone nor the form alone which is the subject and bearer of sense perception, but a *composite unit* made up of both. Consequently, the animal is a composite substance consisting of two incomplete substantial parts. This becomes still clearer, when we consider that, besides sensory functions, the animal also has vegetative functions. The *two types of functions*, however, do not belong to two separate substances in the animal. On the contrary, both types of functions belong to the self same animal: it is the self same animal which digests, grows, sees, hears, feels, runs, and so on, as a single unit of action. Hence, matter and form unite in the animal, not as complete substances, but as part- substances which together make the animal to be a complete, *composite* substance.

Above all, *man* reveals himself as a unitary, complete substance. He possesses the vegetative functions of the plant, the sensory functions of the animal, and the rational functions peculiar to himself. Similarly, he is an extended being consisting of many material parts and bodily members. Now, all these distinct functions and parts do not belong to two or more substances, but to a *single, unitary substance*. Our self-consciousness is witness to this fact. Everything in man is referred to one and the same *Ego* as the ultimate subject and bearer of all. This is evident from the experience of our entire conscious life. Thus, we say: *I* digest, *I* see, *I* walk, *I* imagine, *I* remember, *I* think, *I* judge, *I* desire, *I* love, etc. We perceive ourselves to be, not two or

more things, but one thing. We perceive both body and soul, matter and form, to belong to *one Ego*; we perceive both body and soul, matter and form, to be a single unit of action, a single nature, and therefore a *single substance*. This is a positive and incontrovertible proof that man must be a single, complete, and *composite* substance consisting of 'body' and 'soul' as two incomplete substantial parts or co-principles.

Most hylomorphists also consider the *elemental atoms* and *chemical compounds* to be composite substances, composed of matter and form as two incomplete part-substances. In this respect they would be of the same nature as organisms. Whether this conviction is justified, depends on whether these bodies have a *unitary action* of a type perfectly analogous to that of vital action in organisms. If so, then the elemental atoms and chemical compounds are also composite substances in the sense defined. In this case, the *hylomorphic composition* of bodies would be a *universal fact* of the material world. The defenders of universal hylomorphism point out that the elements and compounds are essentially distinct types and species with essentially distinct properties and activities; this, they say, demands an essentially distinct nature and substance for each element and compound. Their common factor is matter; their distinctive factor is the form. Consequently, also the elements and chemical compounds are in the strict meaning of the term *composite substances*. The hylosystemists, on the other hand, do not consider the elements and compounds to be essentially distinct types and species in the sense that they are genuinely 'unitary

substances.' Their viewpoint will be examined in a subsequent chapter.

To sum up our investigations: Every natural body, at least every organism, contains a passive, material principle and an active, formal principle; these two principles are really, entitatively distinct, and they are called 'matter' and 'form'; matter and form are not accidental, but substantial, principles, and they are incomplete substances; the union of these two incomplete substances (substantial co-principles, part-substances) results in a single, unitary, complete substance which is the subject and bearer of all properties and activities and as such is a composite substance. Hence, every inorganic and organic natural body (or at least every organism) is a *hylomorphic compound*, i.e., a complete substance composed of matter and form. Hylomorphism alone does justice to all the facts and is, therefore, the only true interpretation of the constitution and essence of natural bodies.

SUMMARY OF CHAPTER XII

Hylomorphism is the theory which explains the constitution of 'natural bodies' by means of the dualistic composition of matter and form.

1. The Passive, *Material Principle*. The substance of bodies is entitatively diffused in space. This *diffusion* in space, or extension, is a static, passive, entitative determination of all bodies and presupposes a static, passive, entitative principle which is its foundation and source. And since that is 'material' which occupies space, this principle is a material principle; we call it matter.

2. *The Active, Formal Principle*. Bodies are both 'extended' and 'active.' Extension of itself does not imply activity. Hence, the *activity* of bodies must proceed from an active, dynamic principle; it is called the formal principle, or *form*. Every plant, animal, and man is an *individual unit* with specific properties and activities restricted to the type and species to which it belongs. Since the chemical elements are common to them all, this *specific difference* in organisms cannot be derived from the material elements, but must be derived from a different principle. Similarly, the *unity* and *solidarity*, and also the *purposiveness* of activity in organisms, demand a principle distinct from that of common matter. This is the form. Most hylomorphists defend the hylomorphic composition of elemental atoms and chemical compounds on similar grounds.

3. *Real Distinction of Principles*. The unity of natural bodies proves that matter and form are really distinct, so

that they are different realities and entities. Due to their matter, organisms have a *diversity* and *multiplicity* of parts; nonetheless, organisms are characterized by *unity of essence*, and this unity must, therefore, be due to the form. These being opposite characteristics, they cannot proceed from the same ultimate principle. Consequently, these principles must be really distinct. Notwithstanding the multiplicity of parts in a sensory organ, the *act of perception* is a unitary act. This demands a unitary principle of activity, which is not found in the matter but in the form. Matter and form, therefore, must be really distinct.

The fact of *substantial change* also proves the real distinction. When the elements are incorporated in the structure of an organism through *nutrition*, they change from nonliving to living; and when they leave the organism, they change from living to nonliving; here the elements were changed, while the form or soul of the organism remained the same. In the *death* of an organism, the elements remain in the corpse, but the form has left. Matter and form, therefore, are separable and actually *separated*. Realities, however, which can be separated are really distinct in their entity.

4. *Substantiality of Principles.* The *ultimate reality* in a body is the 'substance.' Matter is universally recognized as being an ultimate and irreducible reality in bodies; hence, it is a substantial principle. The form, too, as the fundamental principle of activity and life, is an ultimate and irreducible reality; hence, it also is a substantial principle.

Organisms, however, possess *essential unity*; they are not two substances, but one substance. It follows, that the

matter and form (soul) of organisms cannot be two complete substances, or the organisms would not be essential units. Matter and form must, then, be *incomplete substances*, substantial co-principles, part-substances.

5. *The Composite Substance.* Every natural body is a *composite* complete substance, consisting of two incomplete substances, namely, matter and form. In the plant, the actions of vegetancy have as the bearer neither the matter nor the form alone, but the whole plant (matter and form) as a *unit*. Hence, it is a composite substance. This is also true of the vital functions of vegetancy and sentiency in *animals*, and of the functions of vegetancy, sentiency, and rationality in *man*; each acts as a single, unitary substance. Hence, matter and form' must unite in every organism, making it a *composite substance*.

Most hylomorphists defend the hylomorphic composition of bodies as a universal fact of the material world, so that elemental atoms and chemical compounds are also considered to be composite substances. The hylosystemists disagree with this view.

Chapter 13

THE HYLOMORPHIC THEORY

HAVING ESTABLISHED THE TRUTH OF THE HYLOMORPHIC composition of natural bodies, at least so far as organisms are concerned, it will be advantageous to scrutinize the *traditional hyломorphic theory* somewhat more in detail. The theory is traditional with practically all scholastics, and as such its main features should be well understood. As here explained, it applies also to chemical elements and compounds, so that no distinction is made in the hyломorphic composition of organic and inorganic bodies, except that the 'form' of organisms is a 'vital' principle while that of inorganic bodies is a 'non-vital' principle; both types of bodies are alike in this, that they are substantially composed of matter and form.

The student is warned not to rely in any way on his imagination. If he attempts to visualize 'matter' and 'form' in images, he will most assuredly fail. It is only by means of *rational concepts* that he may hope to arrive at a correct understanding of the theory of matter and form.

MATTER

All bodies, we know, consist of 'matter.' When we speak, therefore, of the 'matter' of an actual, concrete body, as it exists before our eyes, we speak of matter as it is already actualized by a form; it is *informed matter*. We can, however, *think* of this same matter as something prior to the reception of a form, as something isolated and separated from any form, as something for itself independent of any form. Taken in this latter meaning it is called *first or primary matter (materia prima)*; matter in the former meaning is termed *secondary matter (materia secunda)*. We are here concerned with 'primary matter,' not with secondary or informed matter.

Primary or primordial matter is an incomplete corporeal substance, undetermined but determinable, capable of receiving any kind of substantial form. Primary matter, being one of the two essential and substantial constituent co-principles of which every body is composed, is said to be *incomplete*; by this is meant that matter, of and by itself, is insufficient to constitute a body and must be united with its other incomplete co-principle (the form), so that the complete substance is the result of the union of both co-principles. It is *corporeal* and not spiritual; as such it must have the aptitude to furnish the substrate for the three dimensions of length, depth, and breadth, since these dimensions are the characteristic features of every material substance or 'body.' It is said to be a *substance*, inasmuch as it belongs to the category of 'substance' and not to any of the categories of 'accident,' even though it is an 'incomplete' and not a 'complete' substance; primary matter, therefore, must not be confounded with quantity,

quality, action, or any other modification of bodies. It is *undetermined*. As such, primary matter possesses neither essence, nor quality, nor quantity (*nec quid, nec quale, nec quantum*); these are determinations and actualizations which come from the form, not from matter directly. Primary matter, considered for itself, has no perfection or act whatever; it is *pure potentiality*, devoid of all actuality, in the line of substance. While it is the factor of indetermination in the constitution of bodies, it is an undetermined substantial reality which is *determinable* to any kind of bodily species by means of the form. It is completely indifferent and therefore potential toward all forms; under the influence of the proper efficient causes, it is receptive toward any form which may be demanded by the conditions. Primary matter, therefore, is *capable of receiving any kind of substantial form*, organic or inorganic; it is the common ground or base or substrate for all substantial changes, passing through them all from one kind.

Since it is an incomplete substance, pure substantial potentiality, without determination of any sort, it *cannot exist alone*; it exists only in conjunction with the substantial form in the composite, complete substance or body. What really exists, is the complete substance or body; primary matter has existence only because it is an essential and substantial co-principle, together with the form, of the existing body as a whole. For the same reason, primary matter is not an object of direct creation; the real object of creation is the complete, composite substance, and primary matter is *concreated* with the form in the complete,

composite substance. If primary matter were deprived of the form altogether, it would at that very moment sink back into nothingness. It is never subject to generation or corruption, because that which is generated and corrupted in substantial change is the compound or complete substance.

FORM

The term 'form' has a number of meanings. In its original meaning, it stands for the *shape* of material things. The same material or matter may assume, or be made to assume, almost any shape or 'form'; a piece of clay, for example, may have the form of a cube, a disk, a cylinder, or of the image of a man. The material or matter is indeterminate, while the form or shape determines it to be this or that. This original and common meaning has been taken over into philosophy, so that 'form' means any determination of an indeterminate but determinable reality. In this philosophical meaning, we distinguish between 'accidental' and 'substantial' forms. An *accidental form* is any reality which determines and modifies a complete substance, such as quantity, quality, activity, and so on; it makes this substance to be so or so, for example, hot, hard, colored, magnetic, etc. A *substantial form* is that reality which determines a being in the line of substance and constitutes either the whole or a part of its essence. In spirits (angels) it is the whole of their essential being, so that they are said to be pure forms' without the admixture of corporeal matter; in material substances or bodies the

substantial form is that part-substance which determines primary matter and which, combined with primary matter, gives to a body its specific nature. Since cosmology treats of bodily being, the term 'substantial form' is taken in the latter meaning, and it is in this meaning that the term must be understood in this discussion. The substantial forms of bodies are of two kinds, *subsistent* and *non-subsistent*; subsistent forms survive the dissolution of the organism, because they are spiritual, while non-subsistent forms perish with the dissolution of the organism, because they depend on the union with matter for their own existence. Man's soul, as will be proved in psychology, is spiritual and therefore subsistent; the forms of all animals, plants, and chemicals are material and therefore non-subsistent. Our present examination centers mainly on the 'non-subsistent' forms, as the context will show.

The substantial form is an incomplete, physically simple substance which is the ultimate intrinsic principle of all determination in a body. It is an incomplete substance, inasmuch as the form, like primary matter, is only a part-substance. The form has the natural aptitude and exigency to be united intrinsically with primary matter, and it is from the union of these two part-substances or substantial co-principles that the complete substance or body originates. Neither matter nor form is a complete substance for itself. It is physically simple in the sense that it is not composed of internal or external parts; it is the principle of physical unity in a body and as such must itself be physically one. That, however, presupposes that it is not composite, but physically simple. The substantial form is an ultimate

intrinsic principle, because it is a constitutive part of the bodily essence and substance and not merely an accidental modification of the substance, and because it is, together with primary matter, the last or ultimate ground and source of its being. It is the ultimate intrinsic principle of all determination in a body, because all properties and activities, which differentiate one body from another, are derived from the form. Primary matter is the undetermined, undifferentiated substrate which is the same in all bodies; the form determines and differentiates this common matter, giving rise thereby to specifically different types of bodies. Matter is passive, potential; the form is active, actualizing. Matter has the capacity to be molded into any kind of specific body; the form gives all actuality and molds primary matter into a specific nature. While primary matter is the same fundamental stuff in all bodies, it is the form which makes a body to be this kind of body rather than that, for example, gold to be gold, an orange tree to be an orange tree, a dog to be a dog, and a man to be a man.

The substantial form may be defined in different ways. One definition has been given and elucidated in the preceding paragraph. It is also defined as the 'ultimate principle determining a subject in the line of substance.' Again, it may be defined as 'the primary act of matter.' The meaning in both these definitions is, that the substantial form is the determining and differentiating principle which gives to primary matter its individualized substantial being, i.e., it makes it to be a body and a definite kind of body; it is not an accidental determination which merely modifies in a

secondary manner an already complete and existing substance.

The substantial form *does three things* to a complete material substance or body. It gives to a body its *specific essence*, making it to be 'this' kind of bodily essence rather than another; whatever differentiates one body from another, is due to the different type of substantial form. It makes the body to be a *nature*. By 'nature' we understand the ultimate principle of activity in a being; and since all activity is ultimately derived from the differentiating form, it must be the form which makes the body to be a 'nature' or principle of activity. The form also gives to the body its *essential unity*. Primary matter is the principle of diffusion and multiplicity; if, then, the natural body is essentially a unit, this must be due to the form.

Such is our philosophical concept of 'matter' and 'form' as the two substantial constitutive principles of every natural body.

THE PHYSICAL COMPOUND

In the union of primary matter and substantial form the *natural body*, as a composite and essentially complete *corporeal substance*, has its origin. One must not imagine this union as some sort of mixture of matter and form; or as if they existed side by side, contacting each other. Such a union would be purely external and accidental. It is rather a complete and most intimate intrinsic compenetration (if we may use the term), in which matter and form complement each other and communicate to each other their own

innermost being. The form, through its own being, is the intrinsic determination of the undetermined matter; matter, on its part, receives this intrinsic determination from the form and becomes determined thereby. The imagination is helpless in picturing this sort of union of two incomplete substantial principles into a single complete substance. An analogy might be found in the impression of a seal upon wax, where the impressed image becomes a part of the wax; it must be remembered, however, that this is only an accidental modification of the wax which does not affect its substance, while the substantial form of the wax affects its innermost being, making the common primary matter to be precisely 'wax' and not some other kind of substance.

The natural body is a single, unitary substance and is brought into being through the union of matter and form. One must not overlook the fact, however, that matter and form are entitatively distinct, even in the natural body as it actually exists. Primary matter and substantial form are *physical co-principles*, and the natural body, which results from their physical union, is a *physical compound*. According to the aristotelian-scholastic conception of the natural body, matter and form are not merely two metaphysical aspects of one and the same fundamental reality; they are distinguished from each other as physical realities, so that the natural body is the result of a physical composition of both. Since, however, the product of their union is a single, unitary substance, the real distinction between primary matter and substantial form is not such that each is a subsisting reality for itself.

Matter cannot *subsist* without its corresponding form, nor can the form (except the human soul) subsist without matter. Without any form, matter would cease to exist altogether, and the same is true of the form. They are natural correlatives. It is *the physical compound which exists and subsists*, in the strict sense of the word; matter and form cannot be said to exist and subsist except in and with the physical compound of which they are the constitutive substantial co-principles.

This brings us to the question of the distinction which exists between the natural body as a *physical whole* and its *two constitutive parts*. The answer is: the physical whole is not merely a collection or sum of two entities (matter and form), but a *third reality*, resulting from them. The physical compound is a true 'whole,' a true unit of activity, and the properties of this whole are quite different from the properties of the parts. Since, however, activities and properties flow from the entity of a thing, the compound must, strictly speaking, be an entity distinct from its parts. This does not mean that the physical whole is distinct from its parts in such a manner, that it adds a new entity to the entity of these parts; it means simply that the physical whole is a *new reality* which *includes* these parts in its being; the physical compound 'consists' of its parts, and the parts 'constitute' the compound. The natural body, therefore, does not contain three distinct entities, matter, form, and the compound; rather, the natural body is one complete entity, the physical compound or whole, which results from the union of these two incomplete constitutive parts. The whole is, of course, more than any of its parts

taken singly and separately, and as such it is really distinct from them; the whole is entitatively identical with all the parts taken together, but the whole as a whole is identified only partly with each part as such. This kind of distinction is termed an *inadequate real distinction*.

THE GENESIS OF BODIES

A body can be considered *in fieri* and *in facto esse*; in the first case it is considered in its state of 'becoming,' in the process of its genesis, and in the second case it is considered as the completed product of this process of substantial change. When one body is being changed into another, the new body is said to be *in fieri* during the entire time of the change, from the inception of this change until its completion; once this change is completed, so that the new body actually exists, the new body is said to be *in facto esse*.

What really happens in the genesis of a new body? Three principles are involved in the process: *matter, form, and privation*. By a 'principle' we understand that from which something else proceeds in any manner whatever. According to the hylomorphic theory, these three factors are the principles which account for the genesis of a new body in substantial change. The primary matter passes from the old body over into the new; nothing is lost or gained here. The new body reveals properties and activities specifically different from those of the old: since properties and activities flow from the substantial form, the form of the old body must give way to a new form, thereby resulting in

a specifically different kind of body. This is the purpose of the substantial change, namely, to generate a new body consisting of primary matter and a new substantial form. 'Privation,' as a principle in this genesis, is the lack of a substantial form in primary matter, in so far as primary matter is in a state of *proximate aptitude* for the reception of the new form. Due to the process of change going on in the old body, the circumstances of the body are such that its primary matter now demands the accession of a new form to meet the changed conditions; the body is 'disposed' for the new form as the next step in the genetic process. The primary matter of the old body 'lacks' the presence of the new form which the conditions demand, and it is in proximate aptitude for receiving it; this immediate 'lack' of a required new form is what is meant by the philosophic term of 'privation.'

It must be borne in mind, however, that the form in question here is the *final form* of this particular genetic process. There may be *intermediate forms* which appear in the course of the substantial change of one body into another; in that case, the intermediate forms are transitory and transitional in character, leading to one final form at the end of the whole process. These transitional or intermediate forms merely 'dispose' the primary matter for the final form, at the accession of which the prolonged change comes to a definite rest as completely terminated. Take food, for example. When food is taken into the system, it is mixed with various secretive fluids. These fluids break down the organic compounds of the food, change them into new compounds, and prepare them generally, so that they

are in a suitable condition to be absorbed by the tissues. This complicated process of preparation involves a chain of substantial changes; these changes, in turn, involve the accession of new substantial forms. However, these new forms are not destined to stay and thus end the process; they are intermediate forms which prepare the foodstuffs and dispose their primary matter proximately for the reception of the 'vital form' of the organism. The *ultimate change* takes place when this vital form, which is the *final* one in the series, informs and vitalizes the primary matter of the food. It is the lack of this final form, not the vanishing of any of the intermediate forms, which is termed 'privation.' The absence or lack of 'life' in that portion of primary matter properly and proximately disposed for 'life' is a prerequisite preparation, so that the vital principle of the organism can animate it and change it from food to living tissue; as such, this 'privation' is a true principle of change, because the vitalization of the food proceeds from it in due course.

It will be noted, that *privation is not a cause*. A 'cause' is something which assists in the production of another through a *positive influence* of its own. Privation, being something negative (a 'lack' of form), cannot exert a positive influence in the production of a new body; hence, it cannot be a true cause. Matter and form are true causes in a body. Both contribute in a positive way toward the production of a new body; matter is its positive and determinable substrate, and the form is its positive and determining actuality. Every 'cause' is a 'principle,' because it is something from which something (the new body)

proceeds; it is a positive principle of production. Not every 'principle,' however, is a 'cause,' because it may not exert a positive, but only a negative, influence on the production of something. It follows, then, that matter, privation, and the new form are the three principles which account for the genesis of a new body; two of these three principles, matter and form, are true 'causes' of its production, while 'privation' is only a contributing principle but no true cause.

Matter and form are *intrinsic causes* of a body. They are termed such, because they are constitutive parts of the very essence and substance of the body; without them the body would cease to be a body. The constitutive parts of a body are, quite evidently, 'intrinsic' and not 'extrinsic' to it. *Extrinsic causes* are causes which are external to the constitution of something and change it through their positive agency from without. Most substantial changes are inaugurated and sustained through extrinsic causes acting on bodies. Heat and electricity, for example, are powerful agencies in the production of chemical changes. It was advisedly stated that 'most' (not 'all') substantial changes are inaugurated through the action of extrinsic causes. In the case of the radioactive elements, the substantial change resulting in new elements is entirely spontaneous and not the result of any outside agency; the exact cause of this disintegration and transmutation is unknown.

As these extrinsic causes influence other bodies, they bring about a substantial change. They do this, not directly, but *indirectly*. No substance acts upon another substance directly; it does this through its *properties* and *activities*. These alter the properties and activities of the other body

to such an extent, that a new substantial form is demanded, the old form being no longer capable and fit for the altered properties and activities. Hence, the properties and activities which a body uses to bring about a substantial change in another are *instrumental causes*; that is to say, they act under the direction and control of their own substantial form in producing a result consonant with the character of this particular form, and this form will always tend to produce a result similar to itself. Wheat, for example, produces wheat, and an oak acorns.

Whence the *origin* of the new form? Is it created? Was it present somewhere in the universe, before this new body was generated? How does it come into being? And what happens to the old form after the new form has taken its place? This is one of the most difficult problems in connection with the hylomorphic theory. The hylomorphist answers that new forms are educed out of the potentiality of matter.

THE EDUCTION OF FORMS

There is a natural tendency on the part of the philosopher, due to his imagination, to picture the form as some sort of subsistent entity independent of matter. While this is true of the human form, it is not true of the material forms of chemicals, plants, and animals. This natural tendency is deceptive and misleading, and it has led some thinkers into erroneous views on this subject.

One theory maintains that all substantial forms were *created* by God in the beginning and have actually and

formally *always been* in existence since then. When new bodies are formed in the course of events, one form after the other is taken or drawn out successively from bodies and matter in which they are precontained. Every seed of a plant and animal, for example, contains innumerable precontained forms; one becomes actively united with matter in the plant or animal which develops from a particular seed, and the rest are again passed on in the seeds of this plant or animal.

The same applies, of course, to the substantial forms of chemical elements and compounds. All forms do not unite with matter to produce a compound, because not all possible chemical compounds are actually made and many seeds never give rise to a plant or animal; hence, many forms are frustrated in their purpose. This theory is called *panspermism*, or the theory of involution, or also the preformation theory. Defenders of this theory were *Leibnitz, Malebranche, C. Bonnet, A. Hailer, L. Spalancani, Linné*, and others.

This theory is now obsolete. It must be *rejected* for various reasons. If all substantial forms were actually present in matter from the beginning, a number of unacceptable consequences inevitably follow from the theory. Leaving the human soul out of consideration, material substantial forms cannot exist except in and with primary matter; in that case they must *inform* or actualize the primary matter in which they are present, and thereby a genuine physical compound (chemical, plant, or animal) must result. The consequences are disastrous to the theory. Since any portion of matter may eventually enter in any

kind of chemical compound, plant, or animal, these respective kinds of forms must all be precontained and present in matter. Since a body is placed in a definite species by its form, it would follow that all bodies are at one and the same time a nonliving *inorganic compound* and also a living *plant* and an *animal*; the inorganic forms would make the compound to be a chemical, the plant forms would make it to be different kinds of plants, and the animal forms would make it to be different kinds of animals. That, of course, is absurd, because contradictory; if a compound is living, it cannot be nonliving, and if it is a plant, it cannot be an animal, and vice versa. Furthermore, if this theory were correct, no real *generation* and *substantial change* could ever occur in nature. All that could happen would be that a pre-existing form becomes revealed or hidden; a new body could never be generated and come into existence, because the form was always present in and with a distinct portion of matter. But this is contrary to all experience; new plants, animals, men, and even chemical compounds come into existence through generation and pass out of existence through dissolution. To deny generation and substantial change is to deny the most obvious facts of nature, and any theory which cannot account for such facts is inadequate. Again, if the forms of *living beings* are actually and formally pre-existent in matter, it is unintelligible why they should not be able to *manifest their presence* through vital functions. They must 'inform' the matter in which they are present, or they could not exist at all; but in that case, the compound would be a real plant or animal, and the organism possesses everything necessary to manifest itself

as a living being with vital function. Finally, the theory encounters insurmountable difficulties with regard to *bisexual plants and animals*. Such plants originate through the union of pollen and ovules, and the animals through the union of spermatozoa and ova; each type of germinal particle is of equal importance for generation. Does the male or female particle carry the form of the new plant or animal? Both cannot carry a form or the new plant or animal would have two forms, and its essential unity would be destroyed. If the female particle carries it, why are the male particles so much more numerous? And if the male particle carries it, why are the female particles so relatively few in number? Since both are of equal importance, no assignable reason can be advanced, why the one rather than the other should carry the form of the new body. The theory simply does not explain the facts and must be rejected.

There is another theory which is similar to the involution theory. It maintains that all forms are *inchoatively* present in all matter; these forms are conceived as being, so to say, *germinally* in existence, but not in a state of complete evolution. This modified involution theory cannot solve the difficulties mentioned in criticism of the involution theory itself. After all, these forms, though 'germinal' and 'inchoative,' are *actual forms*; that is the very point of the theory. But if they are actual forms, they must actualize the matter in which they are present. That, however, is essentially the standpoint of the involution theory and involves the same difficulties.

A more plausible theory of the origin of substantial forms is the theory of *creation*. The defenders of this view consider the origin of the form in a new body as an entity entirely new and original, as the production of something completely out of nothing; and that is creation. Reversely, the form of the old body passes out of existence through an act of annihilation on the part of God. This theory solves all difficulties by its appeal to divine power. However, this theory, though plausible, must be *rejected* as inadequate. The fact must not be overlooked that the *generation* of new bodies is a *natural process*. As long as an effect can be explained by the action of an agent from which it manifestly appears to proceed by means of a natural connection of causality, then its production and generation must be ascribed to the action of this *natural cause*, not to creation. God created beings with natural powers and activities; consequently, they must be able to produce natural effects through these agencies, and such effects must be attributed to them, and not directly to God. Now, it is an obvious fact that created beings do actually influence others by means of their powers and activities; in other words, bodies act upon one another and thereby produce effects in one another. New chemical compounds and new organisms originate as the result of such actions; such is the verdict of common sense, science, and philosophy. We must, therefore, assume that the production of new bodies, of new chemical compounds and organisms, is the result of the natural causality of bodies. In the course of this production, new substantial forms originate and old forms disappear. Consequently, the origin and disappearance of

forms must be attributed as a natural process to the agency of created causes, not to a direct creative intervention of God.

Since neither the theory of involution nor of creation is satisfactory, we must look for a different theory to explain the origin of forms. The aristotelian-scholastic philosophers propose as an explanation the theory of the *eduction of the form out of the potentiality of matter*. This theory is also, though infrequently, called *epigenesis*. Every cause precontains its effect within itself, not in the sense that the effect exists in its own proper reality within the entity of the cause, but in the sense that the cause is a principle which has the power within itself to bring the effect from nonexistence to existence by means of a positive influence in the production of the effect. In this sense, different kinds of causes precontain their effects in different ways, depending on the type and nature of their causality. A material cause, such as primary matter, is a cause of production, in so far as it can, due to its potentiality, be changed into the actuality of some form through the agency of an efficient cause. A form, which can come into being through the transmutation of matter, is precontained in the potentiality of matter before it actually 'becomes'; its actual 'becoming' is thus correctly designated as an 'eduction' out of the potentiality of matter,' in order to distinguish this type of production from that of creation where no material cause concurs in the effect.¹ The phrase 'contained in the potentiality' means that something is precontained in another, not according to its actual entity, but according to its *possibility*, inasmuch as it can be brought into being by

this other. The *eduction* (Lat., *ex*, out of, and *ducere*, draw, 'draw out') of the form, therefore, is nothing more than the production of the substantial form as an actuality or 'act' in the subjectively concurring primary matter according to the potentiality or 'potency' which enables matter to receive it in the natural process of change through the agency of efficient causes.

To illustrate eduction, we may point, as an analogy, to the production of the shape of a statue. A block of marble 'precontains' the shape of the statue according to its potentiality, because the marble can be changed into the statue through the agency of the sculptor, although nothing of the 'actual statue' is present in the block of marble before the sculptor begins to carve it. In a similar manner, the substantial form can be said to be 'precontained' in the potentiality of primary matter, because the form can be brought into being in matter under the influence of efficient causes. From the standpoint of actual being, neither the statue nor the substantial form has any existence whatever before production begins; both, however, 'become' or are 'educated from the potentiality' of their respective matter, the one as an accidental modification of marble and the other as a substantial transmutation of primary matter. Just as the chisel of the sculptor can change the marble into the shape of a statue, so the activities of efficient causes in nature can produce the substantial form in primary matter. The statue is a new actuality, but there is no necessity of invoking any creative act on the part of God, because the marble is a concurrent cause of the change which takes place in it; just so, too, there is no creation involved in the production of

the substantial form in the new body, because here primary matter is a concurrent material cause assisting in the production. Creation is the production of a being in its *totality* from a state of complete nonexistence to existence, so that the new being passes from a state of absolute 'not-being' into 'being.' When a new body is produced out of another or others, it is merely the change of 'this-kind-of-being' into 'that-kind-of-being'; since the primary matter passes from one body into the other, receiving in the change a new *substantial determination* (the form), we cannot speak of creation. Hence, wherever a new body is generated, the new form is educed out of the potentiality of matter. Matter is transmuted, and in this natural process it is changed from potency (potentiality) into act (actuality).²

When scholastics deny that the origin of new substantial forms is the result of creation, they have no intention of denying the concurrence of God's activity with creatural activity. They admit this concurrence. But they insist, and rightly so, that the *fieri* or 'becoming' of a new body, and with it the appearance of a new form, is the result of a *natural process through natural means*. When bodies act upon one another, they produce alterations, new qualities, and new conditions, until the old form can no longer sustain its existence under the influence of the producing causes. Thus, for example, when hydrogen and oxygen approach each other through the attraction of their affinity, they act upon each other to such a degree that their qualities are mutually 'toned down,' reduced to a state of relative neutralization, tempered to a certain *equilibrium*; the result corresponds neither to oxygen nor to hydrogen, but to a

compound of both, water. In virtue of this 'disposition,' the old forms of oxygen and hydrogen are unfit for the new situation and must give way to one substantial form combining both elements into a new single substance.

Opponents find a very grave difficulty in this theory of the eduction of forms. They contend that *accidental* realities, such as properties and activities, are supposed to produce *substantial* results. That would mean, however, that the effect is greater than the cause, and that is impossible. In answer to this objection, the advocates of eduction stress the point that properties and activities are only *instrumental* causes acting under the direction and control of their respective substances; these substances are the *primary* causes, so that substances really act upon substances through the intermediation of instrumental causes. The effect, therefore, must be attributed to the substances themselves, and not to the properties and activities as such. The point is well taken. It is a common occurrence in nature, that instrumental causes produce effects greater than themselves, but not greater than the primary causes using the instruments. A statue, for example, is greater than the chisel and hammer which produce it; but it is not greater than the sculptor who wields these instruments: the statue must be ascribed to the sculptor, not to the chisel and hammer. So, too, substantial changes are the product of the *substances* as *primary* causes, not of the accidental properties and activities used as instrumental causes. The objection is invalid.

The *fundamental idea* underneath the theory of eduction is this: Just as an incomplete, nonsubsistent form can *be* with an intrinsic dependence on matter, so it must also be able to become with an intrinsic dependence on matter, because both 'being' and 'becoming' pertain to the same natural order. Since the actual pre-existence and the creation of substantial forms is excluded, the only correct explanation of the origin of forms is their 'eduction' out of the potentiality of matter.

What happens, then, to the *old forms* when the new forms take their place? When the new body originates with its new form, the old form simply disappears, vanishes, perishes, ceases to be, sinks into nothingness. Just as the present new form, before the production of the new body, was actually nothing and then 'became' by being educed out of the potentiality of matter, so the old form is now actually nothing by having been reduced to the potentiality of matter. This is not, strictly speaking, an annihilation of the old form, any more than the eduction of the new form is a creation. The origin and disappearance of material forms are on a par. What is really generated and corrupted is the *complete substance*, the body as a whole; since the form is an incomplete substance, it cannot remain in existence after the dissolution of the body as a whole and ceases to be.

THE UNICITY OF THE FORM

We now come to an interesting and perplexing problem. Can more than one substantial form be present at the same

time in the same matter? All hylomorphists admit as a basic supposition that every natural body consists of primary matter and the substantial form and that the substantial form is the ultimate determination which places the natural body in a definite species.

John Duns Scotus and the scotists maintained a double substantial form in a living organism. One form makes it to be a plant or animal, that is to say, a *living* being; and this form is the *soul*. The other form makes this particular living being to be *this body*; and this form is the *form of corporeity* (*forma corporeitatis*). By 'body' he understands here the 'organized matter' of the living being, inasmuch as it is distinct from the soul as the life-giving principle. Thus, in this view, every living material being consists of a soul and of matter made to an organism by the form of corporeity.

Most scholastics oppose the doctrine of this type of duality or plurality of forms as an *impossibility* in a natural body. The form of corporeity makes matter to be an *organized* body and, since an organized body 'in general' cannot exist, also to be this particular and *individualized* body. On the other hand, the soul makes matter to be a living' body and, since organized matter is necessary for living function, also to be an *individualized* and *organized* body. Both forms, therefore, place the organism in the genus of 'body' and fulfill the same purpose; both also inform the same matter completely. But then every plant and animal would be *two individuals*. It is, however, the view of some neo-scholastics that Scotus' doctrine is the

only one which can furnish a rational basis for the reconciliation of unity with multiplicity.

The problem of the *plurality of forms* in chemical and organic compounds is still acute.

Organisms (plants, animals, men) are without doubt natural bodies, i.e., natural units of action based on a natural unity of substantial being. According to the traditional scholastic view, chemical elements and true chemical compounds are also natural bodies. Whether compounds are inorganic or organic, they are composed ultimately of the ordinary chemical elements. Scientific experimentation proves, that the weights of the elements remain intact in the compounds; that many of the qualities of the elements are retained in the compounds, though in a tempered and rather neutralized condition; and that the compounds, upon dissolution, always revert to the original component elements and to no other.

Hence, in view of the facts just mentioned, the question arises: Do the elements in the physical compounds keep or lose their individual forms? Since they retain so much of their former identity, do they preserve their individuality in the compound? If so, how can we harmonize this with the evident natural and substantial unity present in the compound? How must we consider the many elements to exist in the compound without depriving the physical compound of its *substantial unity*?

This is a difficult and obscure problem. *Three solutions* have been offered. According to one theory, the elements retain their *complete individuality* in the compound. The compound as a whole has its own substantial form, and

each individual element has its own form while in the compound. This theory was proposed by *Ibn Sina* (Avicenna) and *Ibn Roschd* (Averróes), two medieval Arabian philosophers. St. Thomas and St. Albert the Great opposed this doctrine vigorously, on the ground that thereby the substantial unity of the compound is destroyed and the form of the compound as a whole is reduced to a mere accidental modification; if each element is a complete individual in its own right, the compound can be no more than an 'aggregate' united by an accidental bond.

The two remaining solutions are more important. In diametrical opposition to the doctrine of Avicenna and Averróes, *St. Thomas Aquinas* and the great majority of the schoolmen teach that the substantial unity of the chemical compound and organism can be preserved only if and when the forms of the elements *perish entirely*, so that there is but primary matter and *one substantial form* present. Of the substance of the elements nothing remains but primary matter; this alone passes over in its numerical identity into the new body. The new form preserves the general character of the elements as subordinate parts of the whole. The qualities in the compound are *specifically* those of the component elements, but they are *numerically* different from them; the original qualities of the elements have *perished* with the form from which they sprang and do not as such pass over into the compound. The qualities of the new body are entitatively new qualities, and they come into being with the new form.

St. Albert the Great, the teacher of St. Thomas, and other schoolmen take a middle course between these two

theories. They find it incomprehensible how primary matter can exist even for an *instant* without a form, and that would seem to be a necessary assumption, if the elements must first be deprived of their forms before the new form steps in to take their place. In the view of St. Thomas, a plurality or even a duality of forms can never coexist in any manner in a compound. It follows, it would seem, that there must be a moment of time, no matter how small, between the disappearance of the old elemental forms and the new form of the compound, because they cannot exist simultaneously in primary matter; there must be a moment, then, when primary matter belongs neither to the elemental forms nor to the new form, but is alone for itself. Primary matter, however, is a nonsubsistent, incomplete substance and cannot exist except in conjunction with a form at all times; then how can it pass over into the new body without taking the elementary form with it? To assert that the qualities of the new body are 'numerically' different from those of the elements, seems unwarranted; this postulates a *complete gap* in the process of change, and there is nothing to indicate this. The facts rather indicate that they are numerically the same. If it is possible, however, for the elements to retain their old forms in the new compound, then one can understand why the qualities of the compound are similar to those of the tempered elements and also why these elements should reappear after the dissolution of the compound.³ The elements, of course, would not retain their *complete individuality* in the compound, otherwise the latter would not possess substantial unity; they would be reduced in efficiency, their whole entity now being

subservient to the needs of the compound as a whole. Formerly they were individualized units; now they are but integral parts. They have lost their *individuality*, but have retained their reality. An analogy can be observed in the different letters of the alphabet, or in a number of separate lines, or in a set of triangles. Taken singly, each is an individual unit. But if the letters are combined into a word, or the lines into a single longer line, or the triangles into a polygon, they become parts of a higher unity, retaining their reality but losing their individuality; and that is what happens to the elements in a compound. Or, to put it in a different way, the relation between the elements and the compound and between the elemental forms and the form of the whole is like that of a federation of states under a central, federal government: the single states are integral parts of the federation and are under the control of the central government for the benefit of all, but they still have a limited autonomy and a certain amount of self-government within the framework of the federation. This theory of the plurality of forms in a composite body therefore resembles a federated democracy, while the theory of the unicity of the form is more like an absolute monarchy.

The defenders of the plurality of forms realize the difficulty of reconciling their view with the *substantial unity* of the organisms and chemical compounds. But they argue as follows. The form is that through which (*quo*) a being is constituted complete in its substantial and specific being (*esse*). Hence, we cannot assert that the elementary forms remain in the compound *precisely as forms*. Through their

union with the higher form of the compound the elements are elevated to a higher type of unity of being, and their elemental forms no longer determine them in their complete and ultimate being; consequently, these forms lose their character as *ultimate* determinations (forms) and become subordinate determinations, capable of being determined by a higher form. These forms, then, retain their 'reality,' but lose their character as 'ultimate determinations of matter.' It would be a very difficult thing to prove that the same matter cannot be determined by different determinations, at least in part, without begging the very question at issue. If this interpretation of the compound is correct, there is no need for assuming that the elemental forms must vanish and be reduced to nothingness.

The opponents consider this argument fallacious. They cannot understand how the elemental forms can be present in the elements of the compound in any way except *precisely as forms*. A physical compound, whether organic or inorganic, possesses a specific nature. What determines this *specific nature*? The substantial form. It is the precise purpose and function of the form to determine a definite portion of primary matter to its specific nature, e.g., to hydrogen, carbon, oxygen, chlorine, gold, etc. If hydrogen combines with oxygen into water, and if the hydrogen form remains in the compound, can this hydrogen form exist in that portion of matter at all without determining it to the specific nature of hydrogen? Is not 'informing' its very essence? Must it not be present *precisely as a form* and as nothing else? But then this portion of matter is still

hydrogen and not water, or it is both hydrogen and water at the same time, due to being determined by both forms; in the first instance there is no substantial change and no true compound, and in the second instance the same portion of matter belongs to two distinct species of being. The difficulty increases, when we consider the presence of non-living elementary forms present in a living compound; since the whole organism 'lives,' how can the elements constitute living tissue, if the elemental forms remain?

On their part, the defenders of the *unicity of forms* base their main argument on the *substantial unity* of organisms and chemical compounds. Natural bodies are unitary beings of action and possess a single specific nature. This unity of substantial being is due to the form, because the form is the source of all determination in a body. The form actualizes primary matter. Hence, the unity of being presupposes *one form*. Since matter and form are the essential constitutive principles of a natural body, a duality or plurality of forms would necessarily destroy the essential unity of the natural body. Consequently, this unity postulates the *unicity of the form*, so that only one substantial form can be present in any single natural body. With regard to the *tempered qualities* of the original elements, as manifested by the compounds, their presence is easily explained without the necessity of admitting the permanence of the elemental forms in the compound. The superior form contains the perfections of the lower form *virtually*; it is, therefore, natural that the qualities of the compound should be 'specifically' the same as those of the elements. Plants, for example, have a vegetant soul, animals

a sentient soul, and men a rational soul. The animal soul, however, though specifically sentient, also performs the functions of a vegetant soul; and the human soul, though specifically rational, also performs the functions of both the vegetant and sentient soul. Animals do not have two souls, nor man three; but the higher soul contains virtually the powers of the lower soul and performs its functions. On similar grounds, then, every compound must have a single form, while the elemental forms themselves have passed out of existence; the latter are contained 'virtually' in the form of the compound.

The opponents are not satisfied with this explanation of the 'single form.' They offer a most serious *objection*. Imperfections, defects, malformations, and other *abnormalities* occur quite frequently in living beings in the course of their development, which cannot be attributed to external agencies. What is their cause? St. Thomas ascribed such things to the *matter*⁴ which in some way resists the influence of the form or soul. But this seems impossible under the supposition of a 'single form.' How should matter be able to offer any resistance? Matter as such is perfectly indeterminate. Whatever determination it has in the organism it has from the form or soul. Matter, if determined by a single form, can do nothing except in conjunction with this form and only what this form wants it to do. Whatever activities occur in the organism are due to the form, not to matter as such. Primary matter can be molded into anything by the form; it can offer no resistance, because it is supposed to be *pure potentiality*. Under the supposition of a 'single form,' then, these abnormalities must be

ascribed to the form or soul. But that, too, seems incomprehensible, because that would mean that the form, the *sole determinant of the organism*, would *militate against itself*. If, however, we assume that the elemental forms remain in the compound with a certain amount of reduced autonomy, it is conceivable that, under particular conditions, a disproportion might occur which would give rise to such abnormalities.

What are we to think of these two solutions? Do the elemental forms remain in the compound in a reduced state, so that the elements receive their ultimate determination from the superior single form of the compound? Or does the substantial unity of the new body demand the complete disappearance of the elemental form, leaving but a single form in the compound? Both theories possess *probability*.

While hylomorphism is only a *theory*, it must be admitted that it is an ingenious explanation which gives a very good account of the facts in question. It steers a middle course between mechanical atomism and dynamism, harmonizing their true features, while avoiding their defects and exaggerations. It accounts for the passive, quantitative phase of bodies by means of its doctrine of *primary matter*, and for the dynamic, qualitative phase of bodies by means of its doctrine of *substantial form*. There are, of course, obscure points in the theory; that, however, is to be expected, because nature is obscure.

SUMMARY OF CHAPTER XIII

This is an explanation of the traditional hylomorphic theory, as generally accepted by scholastics.

1. *Matter. Primary matter* is an incomplete corporeal substance, undetermined but determinable, capable of receiving any kind of substantial form. It is pure substantial potentiality, possessing neither essence, nor quality, nor quantity.

2. *The Form.* The *substantial form* is an incomplete, physically simple substance which is the ultimate intrinsic principle of determination in a body. It gives to a body its specific essence, its nature, and its essential unity.

3. *The Physical Compound.* Primary matter and substantial form are physical co-principles, and the natural body, which results from their physical union, is a *physical compound*. It is this compound which exists and subsists; matter and form, as such (excepting the human soul), are nonsubsistent, and they exist and subsist only in the compound.

4. *The Genesis of Bodies.* Three principles are involved in the genesis of bodies in the process of substantial change: *matter, form, and privation*. By 'privation' we mean the lack of a substantial form in primary matter, in so far as primary matter is in a state of 'proximate aptitude' for the reception of the new form. Matter and form are intrinsic causes of a body. The properties and activities which bring about substantial changes are *instrumental causes*.

5. *The Eduction of Forms.* Some philosophers maintained that all forms are actually precontained in matter from the beginning of creation. This is the theory of *panspermism, involution, preformation*. If this were true, the same body would belong to different species at the same time, because a form cannot exist without 'informing' matter.

Others maintained the theory of *creation*, in the sense that each new form is the effect of a direct creative act. This theory contradicts the fact that substantial change is a natural process brought about by natural agencies.

The *aristotelian-scholastic* theory is that of *epigenesis*, or the eduction of forms out of the potentiality of matter. A form, which can come into being through the transmutation of matter, is precontained in the potentiality of matter before it actually 'becomes'; its actual 'becoming' is designated as an 'eduction,' so as to distinguish this process from 'creation.' As a thing *is*, so it *becomes*; since the form exists in dependence on matter, so it must also 'become,' and that is 'eduction out of the potentiality of matter.' The old forms simply perish, return into the potentiality of matter.

6. *The Unicity of the Form.* Scotus and the scotists advocate, besides the soul proper as the life-giving principle, a form of corporeity as the principle of 'organized matter' in a living being. Since vital functions demand organized matter, the soul must be able to perform this function, and the form of corporeity seems superfluous; the organism would be two individuals in this theory.

The question, whether the *forms of the elements* remain in the compound, is a perplexing problem. Three solutions have been offered. *Avicenna* and *Averroes* maintained that the elements retain their complete individuality in the compound; but in that case the compound would be a mere aggregate.

St. Thomas and most scholastics defend the *unicity* of the form in the compound. The elemental forms are contained virtually in the form of the compound. *St. Albert* and his followers defend the *plurality* of forms; in this view the elemental forms are present in the compound, but in a reduced state, losing their character as ultimate determinations.

Chapter 14

HYLOSYSTEMISM

OUR EXPOSITION OF ARISTOTELIAN-SCHOLASTIC hylomorphism shows that it is, in its fundamental concepts, a complete and balanced theory which gives a remarkably good account of the chief features of natural bodies. There can hardly be a doubt that hylomorphism is far superior to philosophical dynamism and atomism.

It is well to remember, however, that hylomorphism is but a *theory* and, as a theory, it has value only in so far as the progressive findings of science bear it out. Cosmology is the philosophy of physical nature. The attitude, that cosmology is pure metaphysics and may ignore the conclusions of trained and reputable scientists, is an improper approach to the problem and is contrary to the spirit of Aristotle and St. Thomas. These geniuses based their hylomorphic theory on the best knowledge of their age, and they propounded the theory precisely as an explanation of the scientific data as they knew them. In the face of contradicting facts, they were, as their works prove, the first to abandon a prevailing theory.

Many scholastic philosophers in our day find themselves in this predicament with regard to the traditional

hylomorphic theory as applied to *inorganic bodies*. They admit the correctness of a hylomorphic composition in organism. They claim, however, that the researches of science in the fields of chemistry and physics, instead of confirming hylomorphism, definitely indicate its inability to give an adequate explanation of the constitution of elements and their compounds. They have abandoned hylomorphism in inorganic bodies and substituted for it what *Albert Mitterer* has called *hylosystemism*.

The name is of little importance; but it is convenient to use it here as a designation of these trends of thought among a group of modern scholastics. Their ideas deserve an impartial hearing.

PRELIMINARY OBSERVATIONS

In order to avoid a confusion of ideas, it will be necessary to clarify certain concepts and terms which play a dominant part in this problem of the constitution of inorganic bodies.

The theory that material things are composed of matter and form originated from a consideration of *artefacts*. Bronze, for example, is molded into a statue; wood is fashioned into a bed; brick, mortar, wood, etc., are made into a house. These raw materials (stuff, matter) receive a definite shape or arrangement (form). All manufactured articles and works of art (artefacts) are thus seen to consist of two distinct factors, one indeterminate (stuff, raw material, matter) and the other determinate (shape, form). All artefacts, therefore, consist of matter and form. This is *technical hylomorphism*.

A similar condition is observed to be present in the *sensible appearance of natural bodies*. There are quantitative and qualitative properties which affect bodies and can be perceived by the senses; such are magnitude, volume, configuration, temperature, color, savor, odor, electrification, magnetization, and others. These properties are subject to considerable change. Supporting them, however, is the fundamental reality or substance of the body itself, which remains unchanged and permanent. The substance, as such, is something which cannot be perceived directly by the senses; it is imperceptible, 'metaphenomenal.' These properties are accidents which actualize and determine the substance; they are, therefore, accidental *forms* which inhere in the substance as in their subject. The substance is the supporting substrate of the accidents and as such partakes of the nature of a determinable *matter*. The relation, therefore, between the imperceptible, metaphenomenal substance of a body and its sensible phenomenal accidents is that of 'matter' and 'form.' This is *substance-and-accident hylomorphism*.

Penetrating still deeper into the nature of bodies, Aristotle and St. Thomas centered their attention upon the *ultimate constitution* of natural bodies. They maintained, as was noted in the foregoing chapters, that all natural bodies, organic as well as inorganic, have a hylomorphic composition in their very essence and substance; they are the result of a union of *two substantial, essential principles*, namely, of primary matter and substantial form. 'Matter' is the common factor of which all bodies consist, while 'form' is the distinctive determinant which makes them specimens

of certain types and species. Neither matter nor form is directly perceptible by the senses; they are 'metaphenomenal.' These are the ultimate constituents of every 'natural body.' By 'natural bodies' in the inorganic world aristotelian-scholastic philosophers understand the elements and chemical compounds, the latter resulting from the former by means of a substantial change in their union. For example, iron, gold, water, air, etc., are natural bodies. They agree in this that substantial matter is common to them all; but they differ in this that each possesses a distinctive substantial form, namely, an iron-form, a gold-form, a water-form, an air-form, etc., the 'type' or 'species' of each being determined by the form. This is *substantial hylomorphism*.

While Aristotle, St. Thomas, and their followers were mistaken as to the number of elements and their exact nature in a scientific sense, their *concept of the element* is correct and agrees in the main with that of modern physics and chemistry. The elements are conceived as the fundamental units as to *type* and *species* of bodies. The amount or quantity of a particular element has no bearing on its nature or essence as such. A minimal amount, for example, of gold is just as certainly the element gold as a pound or more of gold; it is the qualitative or, as they would say, formal factor (gold-form) which determines the nature of the element, and that is independent of its amount or quantity. The thinkers of their day had no way of knowing the exact weight or size of the minimal parts into which an element, such as gold or iron, could be fractionated; we call these minimal parts of elements 'atoms,' and modern

scientific methods give us a fair estimate of their absolute weight and size. To these philosophers an element is the *ultimate* constituent of bodies which can retain its *typical, specific identity*. Elements can, of course, unite into compounds, but that is a secondary feature. Hence, an element is an ultimate body; it does not consist of other bodies, but other bodies (compounds) consist ultimately of elements and originate from them. This is also the concept of an element in the science of today, so that the philosophical concept of Aristotle and St. Thomas and the physical concept of modern scientists are in accord.

These concepts, however, *differ* in secondary respects. The older exponents of hylomorphism held the view that the elements are not composed of ulterior particles, but solely of primary matter and substantial form; this is their ultimate mode of composition, and nothing in the elements is prior in existence to these two substantial principles. Scientific research in our day has proved that this view is erroneous; elements are composed of heterogeneous sub-elemental and subatomic particles of matter, namely, electrons, protons, neutrons, and possibly positrons. Mitterer calls these particles *hylons* ($\acute{\upsilon}\lambda\eta$, matter, $\acute{o}\nu$, being; matter-particles). These particles are not 'elements' in any real sense of the term, because they enter into the composition of all elements; the elements represent distinct *types* and *species* of natural bodies, while these particles do not. Quite consistently, St. Thomas taught that a division in an element is a division into primary matter and substantial form and, since matter and form in inorganic beings cannot exist separately, such a division would of necessity destroy

the element entirely, without a vestige of it remaining after the division. This, we now know, is not the case. The disintegration of the radioactive elements (uranium, thorium, actinium, and many of their derivatives) and also the sundering of elements through bombardment prove conclusively that a division of the elements does actually occur without a complete destruction of the entire material of the element. The element does indeed cease to exist as this particular kind of element, but it either changes into a different element or it dissolves into sub-elemental hylons (electrons, protons, etc.).

St. Thomas considered the elements to be the *ultimate bodies*. According to his view, a body is a 'material substance,' a 'corporeal substance.' In other words, every 'material substance' is a true 'body,' and every 'body' is a 'material substance.' Both are objectively identical, though conceptually diverse, things. Inasmuch as he had no knowledge of the ulterior hylonic composition of the element, it was natural for him to identify 'body' and 'material substance.' He was right in stating that the elements are the ultimate 'bodies,' because they are individual beings with a complete identity of their own. On the other hand, protons, electrons, and similar particles cannot be said to be true 'bodies,' because they are really *components of bodies*; they have no full independence of being, because they always tend to unite in order to form the elemental body rather than preserve their own identity in a separated existence. From this it follows that the elements are indeed true 'bodies' and also 'material substances'; the hylons, however, are 'material substances,'

but not true 'bodies.' Hence, a 'body' is always a 'material substance,' but a 'material substance' is not always a 'body.' Consequently, 'body' and 'material substance' are not always objectively identical things.

It is the difference between this old and new knowledge of physical nature which gives rise to the difference in theory which exists between hylomorphism and hylosystemism.

THE CRUCIAL PROBLEM

In order not to argue beside the point, it is imperative to specify with exactness the particular point at issue in which the controversy between hylomorphism and hylosystemism centers.

The single point at issue and the common subject of discussion is the *essence of inorganic bodies*, the *ultimate constitution of inorganic bodily substance*. That, and nothing else, is at stake as the crucial problem to be solved. To be more explicit, the *elements and chemical compounds* are 'natural bodies' in a scientific and philosophical sense, and it is their essence or ultimate constitution which both theories attempt to explain in a rationally satisfactory manner.

The *object* of investigation has remained constant from the time of Aristotle to our own day. It is the ordinary *body* which in its whole concreteness is perceived by the senses of man in his daily observation and experience. Such is every element and compound; for example, carbon, iron, lead, gold, mercury, glass, quartz, water, ammonia. Science

has discovered many more elements and compounds than were known to the ancients; but that does not alter the fundamental situation. Aristotle, St. Thomas, and their followers were greatly mistaken in their classification of elements and compounds; but that, too, is only incidental to the question. The important thing for ancient and modern science is the fact that they agree in the existence of elements and compounds as 'natural bodies.' It is not a question of which particular bodies should be designated 'elements' and which 'compounds'; that is not a philosophic problem. Rather, the problem revolves around the question: What is the essential constitution of any natural Inorganic body, whether it be an element or a chemical compound? Beyond the sensible appearances or phenomena of all natural inorganic bodies lies the imperceptible, metaphenomenal bodily *substance*; and that has not changed in the course of the centuries. Iron, gold, water, glass, etc., reveal the same properties at all times, and their physical description is identical in the past and in the present. There is no reason to assume that the types of bodies themselves have undergone any fundamental change in the course of the earth's development. Hence, it is logical to assume that they have retained their essence and substantial being intact. The problem, therefore, of the modern philosopher is the problem which confronted Aristotle and St. Thomas.

There is, quite naturally, a difference in the *approach* to the problem. The knowledge of the older cosmologists was pre-scientific and depended entirely on the observation of the unaided senses. Modern cosmologists are more fortunate. With the assistance of the microscope,

spectroscope, Wilson chamber, cyclotron, and other appliances, bodies have been forced to manifest their properties more accurately and fully, so that cosmologists are in a better position to infer the ultimate constitution of the corporeal substance underlying these properties. One result of improved scientific method is the knowledge that stars and other heavenly bodies are composed of the same elements as earthly bodies; it is, therefore, no longer permissible to accept the view of Aristotle and St. Thomas that heavenly bodies consist of a special element (aether) and are unchangeable. The entire universe, excepting organisms, is composed of the same types of bodies possessing the same substantial constitution.

We are, then, not concerned with the ultimate, substantial constitution of this or that particular element or of this or that particular chemical compound. Nor are we interested primarily in the nature and constitution of such sub-elemental particles as electrons, protons, neutrons, and so forth. The standpoint of the problem would be unjustifiably shifted, were we to focus our investigation on these realities. It cannot be stressed enough that the point at issue between hylomorphism and hylosystemism is entirely and solely the question of the ultimate constitution of any and every natural inorganic *body in general*, no matter of what kind, and of the *elements and compounds as such*, no matter what their type and species. Hence, it makes no difference whether there be five elements, as Aristotle and St. Thomas taught, or 92 elements, as present scientists teach; nor does it make any difference whether an element be mistaken for a compound or a compound for

an element: the problem is still the same. The natural inorganic bodies are simply *elements* and *chemical compounds*, and it is the correct theoretical and philosophical explanation of their essence which is at stake. Both theories must accept the data of science concerning the physical nature of inorganic bodies and, with the aid of these data, seek to penetrate the veil of phenomena and discover the underlying constitution of the corporeal substance which is the source of the properties we perceive in bodies.

THE TWO THEORIES

Both theories seek to determine the essential constitution of corporeal substance. Both admit that corporeal substance (body) is not a simple substance, but composite; that the natural body originates from a union of its component parts; that the result of this composition is the individual substance of the body; and that this inner constitution of the corporeal substance is its *essential* and *ultimate constitution*, namely, the final and innermost ground of all its properties and activities. They differ, however, most radically in their explanation of this ultimate constitution.

We are already familiar with the basic ideas underlying *hylomorphism*. It explains the composite substance of the natural body by means of *primary matter* and *substantial form*. In this it takes as its technical model the 'statue,' where the raw material of bronze receives some definite shape or form. *Hylosystemism*, on the other hand, explains the constitution of the natural body as an *atomary energy*

system, in the sense that the atom of an element and the molecule of a compound are composed of subatomic particles (protons, electrons, etc.) united into a *dynamic system* working as a *functional unit*. The differences between the two theories should be carefully noted.

The *first* difference lies in the *essential parts* which make up the substance of the body. In the aristotelian-thomistic philosophy, elements and compounds consist of but incomplete substantial parts, namely, primary matter and the form. In hylosystemism, which follows modern science closely, chemical compounds consist of individual molecules, molecules of individual elemental atoms, atoms of nuclei (protons, neutrons, positrons, electrons) and planetary electrons, and finally of energy particles (quanta, photons). The old theory is, therefore, hylomorphic, while the new theory is hylomeric (Gr., ὕλη matter, μέρος portion, part, particle; matter-particles).

The *second* difference. Hylomorphism rests upon a *dualistic* or *binary* conception, inasmuch as matter and form are the only constituents of any body, be it element or compound. Neither primary matter nor the substantial form consists of any ulterior parts. Hylosystemism is based on a *pluralistic* conception of the body, both for the element and the compound. The number of constituent particles varies considerably, increasing progressively in the elements from hydrogen to uranium and mounting into many hundreds in the more complicated compounds.

The *third* difference. In hylomorphism the essential parts, matter and form, are not complete substances, but *incomplete substantial principles*. Matter is undetermined

potentiality, and the form is determining actuality; the 'complete substance' is the result of their union. In hylosystemism the essential parts are *complete substances*. The chemical compound 'water,' for example, consists of atoms of oxygen and hydrogen, and they are complete corporeal substances; these atoms, on their part, consist of hylons (protons, electrons, etc.) which are complete material substances.

The *fourth* difference. The hylomorphic composition of a natural body, since it consists of nothing but matter and a single form, brings about a complete *homogeneity* throughout the entire extent of its substance; gold is gold throughout, bone is bone throughout, water is water throughout. The hylomeric composition induces a *heterogeneity* of parts in varying degrees of co-ordination and subordination, inasmuch as elements are composed of numerous hylonic particles and compounds are composed of distinct elemental atoms.

The *fifth* difference. The hylomorphic substantial parts of a body, matter and form, do not exist in a spatial side-by-side-ness within the body; they *interpenetrate* each other as potency and act in a most intimate union, so that they constitute a single reality and substance. The hylomeric parts, on the contrary, never commingle but stand apart from one another with *space between them*. It is possible that the protons and electrons of the nucleus are in contact, but the planetary electrons are stationed at a relatively great distance from the nucleus. Hence, the hylomorphic body is a *unitary substance*, while the hylomeric body is a *system* of corporeal and material substances. The technical

model for the unity of the hylomorphic body is the 'statue'; the technical model for the unity of the hylomeric body is the 'house.'

HYLOMERIC CONSTITUTION

The problem before us is the problem of the *essential constitution* of physical bodies. It will, therefore, be necessary to investigate the requirements of such a constitution. All agree that the main requirements are as follows.

It must really be a *constitution*. That is to say, there must be parts, and these parts must be united into a whole which is something more than the mere numerical sum of the parts. For example, one hundred cents, placed side by side, are a dollar, but they do not coalesce into any sort of higher unity as a whole; on the other hand, two atoms of hydrogen and one of oxygen unite into water, and water is a whole which is something different from mere hydrogen and mere oxygen in juxtaposition.

This constitution must be *natural*. The parts must unite into a whole as a result of natural tendencies, and not through extraneous constraint. Such a constitution is a natural product, not an artificial construct. A chemical compound is a 'natural' whole; a toy is an 'artificial' whole.

This constitution must be such that the whole is brought about and sustained by the *intrinsic powers* of the parts themselves (*per se*), not by outside agencies (*per accidens*); otherwise the physical body would not be a natural, individual unit.

Since it is the question of the essential constitution of physical substance, the component parts must be *substantial parts*, either complete or incomplete. The union of a substance with its accidents is not the point at issue.

This constitution must be the ultimate ground for the *species* of the physical body. It must, therefore, account for the fact that gold is gold, that helium is helium, that water is water, that sodium carbonate is sodium carbonate, etc.; it must explain in a satisfactory manner the common and distinctive properties of the elements, the periodic recurrence of similar properties among the elements, their gradual increase in weight, their valence, their stability, their typical character, etc.

The advocates of hylosystemism are emphatic in their claim that a hylomeric constitution is a *real essential constitution* in the sense specified and fulfills all the requirements demanded by an essential constitution.

The hylonic parts (electrons, protons, neutrons) are real parts which combine to form a *whole* (the atom, molecule), and this whole is certainly more than the mere numerical sum of its constituent parts. Their union effects a real energy system which acts as a functional unit. Just as a house is more than the sum of all the bricks and strips of wood, so the atom is more than the sum of the electrons, protons, and neutrons.

This hylomeric constitution is *natural*, because it is brought about by the natural tendencies of the subatomic particles and not through extraneous compulsion. The parts of a house have no tendency to combine, so that their union would produce a definite structure; that is why a house is

an artefact. The atom, however, is a natural structure, produced by the natural forces inherent in the particles.

The hylomeric parts are the *intrinsic cause* of the whole, so that the whole is constituted through the agency of these very parts (*per se*, not *per accidens*). Because of this fact, the atom is a natural individual unit of action, and not a mere aggregate of separate substances drawn together by an outside agency.

The parts which constitute the bodily substance must be *substantial* parts. The hylonic particles (electrons, etc.) are certainly substantial, just as substantial as primary matter and substantial form in the hyломorphic theory. No valid reason can be advanced why it should be impossible for a substance to be the resultant of a combination of other actual substances.

There is no contradiction in the idea that the *specific essence* of a bodily substance could be the result of a hylomeric constitution, so that the latter is really the ultimate ground of the species of the body and of its specific properties. On the basis of such a hylomeric constitution there is a rational explanation for the specific properties so noticeable in the elements, such as atomic number, atomic weight, valence, the series and group arrangement, the periodic recurrence of similar properties from Zero element to Zero element, the existence of transitional elements, the disintegration of elements, the absorption and emission of definite energy quanta, ionization, spectral lines, and so forth. Because atoms are systems of particles, it is understandable why elements are relatively stable and typical, why there are isotopes and isobars, why chemical

compounds always revert to their original elements, and why all elements can be broken down into homogeneous electrons, protons, and neutrons, why an increase or reduction of the unit electronic charge and mass never occurs, why the nucleus has practically all the mass of the atom, why the atom occupies a much larger space than the actual matter contained in the atom demands, and so on. The system or structure of the atom and molecule accounts in an admirable manner for all these phenomena revealed by modern physics and chemistry.

HYLOSYSTEMISM VS. HYLOMORPHISM

The decision between hylosystemism and hylomorphism depends upon which of the two theories can give the most logical and rational explanation of the physical facts manifested by natural bodies (elements and compounds). This was, and still is, the purpose for which they were devised. Every hypothesis rests upon some *fundamental assumptions*. These assumptions will be either verified or refuted by subsequent discoveries. If these discoveries bear out more and more (as they should) the primary assumptions, then the hypothesis is strengthened and gradually nears verification. If, however, these discoveries, as they increase in number and accuracy, tend to show that the primary assumptions are incorrect, then the hypothesis is weakened and may finally be discredited entirely. If the primary hypothesis or theory, following increased and perfected knowledge, must be bolstered by an auxiliary

hypothesis or theory, it is usually a sign that the original assumptions were inaccurate or untrue.

The defenders of hylosystemism contend that the fuller knowledge of inorganic bodies, as revealed by modern physical science, shows that *hylosystemism* and not hylomorphism, gives a better and more rational explanation of bodies. The facts do not favor hylomorphism. In other words, the data of the empirical sciences demand a *hylomeric constitution* in elements and compounds, not a hylomorphic constitution.

Consider the question of *minimal parts*. Both theories admit that bodies are, as a matter of fact, not capable of infinite physical division. Through division one must ultimately arrive at *minimal parts*. Science has proved this beyond reasonable doubt: chemical compounds cannot be divided beyond molecules, nor elements beyond atoms, without losing their individual identity. This fundamental assumption of 'minimal parts,' however, receives a valid theoretical explanation only on the basis of a *hylomeric constitution* of bodies.

We must bear in mind, that there is a very *definite limit* to such a division and that the minimal parts (atoms and molecules) have a *determinate size and mass*. There is nothing in the theory of hylomorphism to account for this. Water, for example, is a totally homogeneous substance, according to the aristotelian-thomistic conception, consisting of nothing but a certain quantity of matter and a single water-form. No valid reason can be assigned, why this water substance, in itself, should have a definite limit of division and should have minimal parts of definite size and

mass. Since water is a totally homogeneous substance, there should be no intrinsic limit to the division of this substance; the only limit would be the extrinsic one of the lack of proper technical instruments. Actually, however, such a definite limit exists, and the minimal parts have a definite size and mass. The necessity of this is readily explained by the hylomeric constitution of elements and compounds. The atoms of hydrogen and oxygen consist of a definite number of protons, neutrons, and electrons, and the molecules of water consist of a definite number of atoms of hydrogen and oxygen. It is impossible to divide water beyond the definite limit of the molecules, each of which naturally has a definite size and mass; a division beyond this limit would break up the water molecule into the atoms of hydrogen and oxygen. Similarly, a division of the atoms would result in nuclei and electrons. The hylomeric constitution of elements and compounds thus contains a logical and adequate ground in itself for the existence of definite minimal parts.

Science has proved empirically that the minimal parts of various types of bodily substances *differ* considerably in their *size* and *weight*. Osmosis, for example, shows that the molecules of sugar and water are not of the same size. The periodic table brings out the fact that atoms of elements increase progressively in weight from hydrogen to uranium. The hylomorphic theory can give no theoretical constitutional reason for this. According to the principles of this theory, the minimal parts consist of nothing but primary matter and substantial form. No intrinsic reason is given, why a particular form should demand more matter in one

minimal part (atom) than in another. The reason in a hylomeric constitution is plain. An atom is not a homogeneous substance. It is a system of hylonic particles, and this system contains progressively more particles from element to element. It follows as a matter of course that the atoms of elements and the molecules of compounds must differ both in weight and size; their constitution, being hylomeric and not hylomorphic, demands this difference as a result of the variation in the number of the component particles. It will thus be seen, the hylosystemists claim, that a hylomeric constitution alone, on the basis of the theory as such, gives a rational explanation of the existence of minimal parts in bodies. Hylomorphism merely 'assumes' that bodies have minimal parts, but there is nothing in the theory itself to explain *why* there should be minimal parts of definite and differing size and weight.

Then there is the question of *substantial change*.

The bodies in the universe are all *individual* bodies, each having an individual existence. Each body possesses a *generic* feature and a *specific* feature. Inasmuch as all bodies are material, corporeal substances (or simply 'bodies'), they are generically alike. Inasmuch, however, as they vary according to definite type (for example, carbon, oxygen, gold, radium, etc.), they are specifically different and belong to various species. Now, it is universally recognized that individual bodies do not remain permanently in the same species. Though they retain their generic character as 'bodies,' they change their 'species' by passing from one type into another type. From one kind of substance they become a different kind of substance. This is

a matter of 'substantial,' or 'specific,' change. For instance, radon changes to helium, hydrogen and oxygen become water, wine turns into vinegar. How explain the fact?

Obviously, since each such substantial or specific change means a *constitutional change* on the part of the changing bodies, the explanation must be sought in the *essential constitution* of the bodies themselves. Aristotle was convinced that he had found the solution of the problem of substantial change in the theory of primary matter and substantial form. Changing bodies retain their 'generic' character, but lose their 'specific' character; they retain 'primary matter,' which is common to all bodies, and lose the 'form,' which is specific for them. The constitution of inorganic bodies, therefore, is such that they consist of these two essential co-principles and of no more. They are the ultimate realities of all bodies. St. Thomas followed Aristotle in this theory of hylomorphism. Both based the theory on what seemed to them, in their limited observational knowledge, to be indubitable facts.

The hylosystemists, however, are convinced that a deeper knowledge of the facts militates against the theory. The theory, they claim, fails to explain the very facts for which it was devised, and no greater calamity can happen to any theory. In *substantial change* Aristotle and St. Thomas saw one of the most potent arguments in favor of the matter-and-form constitution of bodies; and if it fails to give a satisfactory account of substantial change, the theory is ruined in its very foundation.

Substantial change, as envisioned by the hylomorphism of Aristotle and St. Thomas, was a relatively simple process.

An individual bodily substance, for instance, this wine, changes substantially by turning to vinegar. Through the efficient causality of external agencies this body becomes unfit for the wine-form, which is the specific constitutional factor in the substance of the wine. The wine-form leaves the primary matter, which is the generic constitutional factor in the substance of the wine, and gives way to the vinegar-form, the new specific factor. The body has changed from the substance wine' to the substance 'vinegar.' The process involved nothing more than the loss of the old form and the acquisition of the new form. This accounts for the fact that the body retains its generic character (material, corporeal substance), but changes its specific character (wine to vinegar).

According to the *hylosystemistic theory*, much more remains than primary matter and much more changes than the substantial form. The structure of the elemental atom is a complex system of hylonic particles. This was pointed out before. The atom and molecule, from all the evidence accumulated by science, is a *hylomeric structure* of heterogeneous material, not a homogeneous, uniform substance. This is something very different from the binary constitution (matter and form) of Aristotle and St. Thomas. There is nothing to indicate that electrons and protons coalesce into a solid mass. On the contrary, the facts indicate plainly that electrons, protons, and neutrons retain their identity in the atom, that the atom consists of a nucleus and orbital electrons, with considerable intervals of space between them. When, therefore, atoms break down, either partially or totally, they resolve themselves into

material particles which have an existence of their own outside the structure of the elemental atom. This is at variance with the suppositions of hylomorphism, because more remains after this substantial change than mere primary matter. Similarly, in chemical displacements we notice groups of atoms, called radicals, which react as if they were a single atom; as such they have valence and go in and out of compounds as a unit. Hylomorphism cannot explain such a phenomenon, because, according to this theory, there can be nothing present in a compound but primary matter and a single form. Hylosystemism, with its hylomeric constitution of bodies, alone is capable of explaining such and similar phenomena. When the hylonic particles remain intact in the structure of the atom, and when atoms preserve their individual and group identity in the structure of the molecule of the compound, it is possible to understand the processes of ionization, isotopism, displacement, isomerism, and polymerism.

Furthermore, more changes in substantial change than the form. Substantial change is a change of *system, matter, and energy*. Hylomorphism, of course, also maintains that accidental forms change with the substance. This change of accidents, however, is not an integral part of the substantial change within the substance itself nothing changes but the substantial form. The theory could not take cognizance of the concomitant change in structure, matter, and energy as integral factors, because these things were unknown at the time. It is the change in structure, in the amount and arrangement of the material particles of the atomic and molecular system, and in the energy content of the system,

which brings about the change of one type of body into another. This presupposes a hylomeric, not a hylomorphic, constitution. It is not the technical hylomorphic model of the 'statue' with its intimately united matter and shape which fits the facts of physics and chemistry, but the technical hylomeric model of a 'house' as a system composed of many heterogeneous materials. One set of materials can be replaced by another; the materials may be removed, exchanged, or rearranged, so that the result will be a different type of house. Or to take a different simile, the letters of the alphabet, though each preserves its individual identity, can be arranged in various ways, resulting in words of entirely different meaning. Thus, the letters 'o,' 'p,' 's,' 't,' can be made into 'post,' 'pots,' 'spot,' 'stop,' and 'tops.' In a similar manner, a change in system, material particles, and energy content will give rise to a new bodily substance. Hylomorphism and hylosystemism are opposing theories, each attempting to render an adequate account of substantial, specific changes in bodies. Of the two, hylosystemism seems to give a better theoretical constitutional explanation of the facts.

Again, according to the principles of hylomorphism, no substantial change can occur in a body in consequence of the forces inherently present in the changing body itself. Since primary matter, being 'pure potentiality,' has no powers and activities of its own independent of the actuating form to which it is united, no opposition to the existing form can originate from primary matter. Nor can any change originate from the form, because the form is physically simple in being and cannot oppose itself. Hence,

it is but logical for hylomorphism to state that *only forces extraneous to the body itself can inaugurate a substantial change in a body*. In this manner hylomorphists link the fact of bodily change with the axiomatic principle of movement in general: 'Whatever is changed, is changed by another (*quid quid movetur, ab alio movetur*).' But this is contrary to fact. The *radioactive* elements change *spontaneously*. No extraneous agencies, physical or chemical, are capable of starting, hindering, retarding, or accelerating the spontaneous substantial change which occurs within these elements. The hylomorphic theory fails completely, on the basis of its own fundamental principles, to account for the fact; if hylomorphism were correct, such a phenomenon would be impossible.

There is another fact in connection with the radioactive elements which deserves special consideration. Such elements unite with others to form compounds. Thus, radium, for example, combines with chlorine (radium chloride) and with sulphur (radium sulphate). While in such a compound, a portion of the radium simultaneously decomposes into radon. Here a *partial* substantial change occurs in the very substance of the compound. It is a cardinal principle of hylomorphism, that in a chemical compound there is nothing but primary matter and a single form; the elements lose their identity and are only virtually, not actually, present. Hence, radium and chlorine have disappeared completely as radium and chlorine, having been replaced by a single substance, the compound radium chloride. In that case, however, it is incomprehensible how this remarkable phenomenon should occur. It is only on the

supposition that radium and chlorine *retain their identity in the compound* that one can understand how radium can be transmuted into radon, while it is a part of the compound. And this is impossible, if the constitution of radium chloride is hylomorphic.

Granted, on the other hand, that the constitution of the atoms of elements is *hylomeric*, so that the atom of radium is a system of particles which always retains its essential identity, even in a compound, the facts are readily explained. The nuclei of radioactive elements are of an extremely complex character, containing a large number of protons and neutrons. It would be quite natural that they are unstable and capable of emitting alpha and beta particles, thereby changing from one type of substance to another. Similarly, since the molecule of the compound, for example, radium chloride, is a system of atoms, in which both the radium and chlorine atoms retain their essential identity as systems, it is clear that the transmuting process of radium into radon would continue without interference in the compound. Without a hylomeric constitution such substantial changes are not only inexplicable but impossible.

Hylosystemism, therefore, and not hylomorphism, gives a more rational theoretical explanation of the facts of substantial change in inorganic bodies, as given by the data of scientific research. The findings of science have not confirmed the theory of hylomorphism; on the contrary, they have persistently increased the difficulties to such an extent for hylomorphism, that the theory cannot be said to

fit the facts. The facts overwhelmingly favor the hylomeric constitution of bodies.

These are a few arguments — there are many more — which hylosystemists urge against hylomorphism.

MODERN SCHOLASTICISM

Although present-day scholastics, as a rule, defend the hylomorphic constitution of bodies in principle, many no longer advocate it in the complete manner proposed by Aristotle and St. Thomas. The facts of science have forced them to modify their views; but very many are reluctant to discard completely the time-honored theory.

Many, accepting the structural atom and molecule of physicists and chemists as a fundamentally correct interpretation of facts, find grave difficulty in reconciling such an atom or molecule with the aristotelian-thomistic *single form*. The difficulty lies in this. The atom is the ultimate natural body among the elements, and the molecule is the ultimate natural body among the chemical compounds. As such, each can possess but a single substantial form, if traditional hylomorphism is correct. But how is this possible? The material form is non subsistent in itself and cannot exist except in conjunction with primary matter; similarly, primary matter is non-subsistent in itself and cannot exist except in conjunction with the form. Only the individual body, which is *informed matter*, can have existence. Hence, each particle of matter, which has a separate existence for itself, must possess a separate form. Now, the atom consists of electrons, protons, and neutrons

(nucleus and orbital electrons) which are spaced from one another by relatively large distances and possess a separate existence of their own within the confines of the atom as a whole. Each particle, then, should have a distinct substantial form. That being so, how can there be a single form actuating all particles as a unit? Traditional hylomorphism admits but a single form for a single natural body, and the atom, as all agree, is such a natural body. If the space-separated particles (electrons, etc.) have no special form of their own, but only the single form of the whole atom, how can this single form traverse the intervening gaps of space? Since it cannot exist outside matter, and there being no matter (in the accepted sense) between the nucleus and the orbital electrons, there seems to be no possibility for the one form to inform all the parts of the atom at once. In that case, however, it fails in its essential function.

A number of theories have been advanced as a solution of this difficulty. *One theory* places the form in the nucleus. This hardly solves the problem. The nucleus itself, to all indications, is not a continuous substance, but consists of distinct particles (protons and neutrons), as can be seen in the ejection of alpha particles in radioactive transmutation; so the difficulty remains. Besides, in this view the orbital electrons would not be an integral part of the body of the atom; but that they really are. *Another theory* postulates that the single form bridges the gap between all particles of the atom by also informing the intervening aether, so that the electrons, protons, neutrons, and the intervening aether, enclosing all these particles, are welded together

into a continuous substance which is the entire body of the atom. In this manner a single form is capable of informing all at once. This is an ingenious theory. There is, however, one bad feature about it. In order to save the primary theory of hylomorphism, this auxiliary theory had to be invented. This in itself reveals the desperate straits into which the primary theory has fallen. And now a new difficulty arises. There is no evidence for the auxiliary theory in the data of science; the auxiliary theory is a pure assumption, devised solely for the purpose of being able to maintain the original theory in the face of adverse facts. Besides, if it is true that the orbital electrons whirl around the nucleus at enormous speeds, it is hard to grasp how they and the surrounding aether can unite into a continuous substance. The theory is weak. *A third theory* admits that the data of science make a single form for the whole structural atom impossible and relinquishes the idea of a single form for the whole atom entirely. In its stead it postulates that the *single electrons and protons* possess substantial forms, while the atom and molecule as such are merely *aggregates*, accidental units, of electrons and protons united into a system. In this manner it attempts to do justice to all the facts. However, in doing this, it abandons the fundamental position and purpose of aristotelian-thomistic hylomorphism. Traditional hylomorphism was devised expressly for the purpose of explaining the typical character of natural bodies and of substantial change in a *constitutional* manner. According to this modified hylomorphism, atoms and molecules are no longer natural bodies, and all changes are merely

accidental, not substantial, changes. But this deprives hylomorphism of its very reason of existence and destroys its foundation completely.

On their part, the hylomorphists among the scholastics find hylosystemism unacceptable. In their view, a hylomeric constitution of natural bodies is impossible, because *it has no essential principle of unity* for the system of the atom and molecule. All particles (electrons, protons, etc.) being complete substances in their own right, their combination into a unitary system cannot be adequately explained. To make a new unitary substance of these diverse particles, a substantial principle is needed which has a dominating *dirigitive* influence over all, in order to weld them into the stable, typical body which is the atom or molecule. The system of hylomeric particles, as given in the theory of hylosystemism, is but an *accidental aggregate*, not a natural body. To this the hylosystemists reply that nature provides us with examples of such natural systems through the agency of natural forces, without the necessity of appealing to any separate substantial principle which would be required to effect the unity of the system. An instance is found in the solar system. The sun acts like the nucleus of the atom; the planets, moons, comets, and asteroids congregate around the sun in a system just as the electrons, etc., cluster around the nucleus. There is this difference, however, and the difference is to the advantage of the atom. The solar system is brought about by gravitational force alone; besides this force, the particles of the atom are brought into mutual co-ordination and subordination by the added influences of electromagnetic

forces and energy quanta. Surely, if heavenly bodies can arrange themselves into a system through the causality of gravitational force, there can be no serious objection against hylonic particles forming the system of the atom through a balancing of their own inherent forces. And as for the charge that such a system is only an accidental unit, that is a matter of definition. When complete substances combine into a system in virtue of their own *intrinsic powers* and in virtue of their own *intrinsic tendencies*, such a unity is *natural* and cannot be said to be 'accidental' in the sense that it is foreign to the nature of the parts and extraneously imposed.

Even so, hylomorphists say, hylosystemism offers no explanation of the *essential difference* which exists *between electrons and protons*, the ultimate components of all bodies. Why are they so radically diverse as to mass and charge? This can be explained in no other way than by a hylomorphic constitution; matter is their common component, substantial from their specific factor. Hylosystemists answer that one may accept, if one so desires, a hylomorphic composition in the subatomic particles. The point at issue, though, is the essential constitution of the *natural, individual bodies* as exemplified in the elemental *atom* and the chemical *compound* which are involved in substantial change. Hylomorphism has been pushed from one defensive position to another, from gross bodies to molecules, from molecules to atoms, from atoms to hylonic particles; if it was inadequate to explain the former, it will in all probability be found wanting in the latter. And besides, why should it be impossible for these

hylonic particles to be simply different particles of matter endowed by the Creator with different quantitative and qualitative properties? After all, the hylomorphists must also appeal to the Creator to explain the different types of substantial forms and their particular properties.

Again, hylomorphists assert, why overthrow hylomorphism for the sake of *scientific speculations*, when it is a well-known fact that scientists have reversed their opinions time and time again? This is true enough, answer the hylosystemists. But, was not hylomorphism devised for the purpose of explaining supposedly scientific facts? Aristotle's hylomorphism superseded the primitive cosmological theories of his predecessors, because his theory seemed to give a better explanation of the physical facts as then known. We can do no better than apply the same principle and method to the findings of the science of today. Science advances incessantly. If we waited until science has reached the end of its researches, we would be compelled to wait until doomsday, and cosmology would be impossible. And in that case, Aristotle and St. Thomas were wrong in formulating their theory of hylomorphism.

Accepting, then, hylomorphists might say, the available data of science, many eminent physicists now hold the theory that subatomic particles are rather 'diffused masses' than 'discrete particles.' According to this latest view, the atom does not contain any empty space between the nucleus and the orbital electrons; the entire atom consists of continuous matter, and the protons, neutrons, and electrons are nothing more than 'condensations' of this *continuous matter*. This is a formidable argument, if the

facts are as stated, because this view of the atom agrees to a very large extent with the aristotelian-thomistic concept of ultimate bodies. On the other hand, hylosystemists might answer, the theory of 'wave-matter' is still in a highly speculative stage and labors under serious difficulties (see *The Atom and Wave Mechanics*). The experiments with vacuum tubes, the Wilson chamber, X rays, etc., seem to establish definitely that subatomic particles possess bullet-like properties and must, therefore, be discrete and solid particles of matter.

Finally, hylomorphists contend, if the constitution of bodies is hylomeric, there can be *no real substantial change*. If atoms and molecules are mere systems in which the component parts retain their identity throughout, what is called 'substantial change' is nothing but the grouping, regrouping, and degrouping of these parts; that is not substantial change in any real sense of the term. Hylosystemists answer this serious charge as follows. The 'substantial change' which must be explained, is the change which actually occurs *in nature* and which occasioned the rise of the two theories as an explanation. Hydrogen and oxygen, in a chemical and philosophical sense, are different substances; their combination results in water, which is, also in a chemical and philosophical sense, a new substance. This is the 'substantial change' which occurs in nature, and it is the only kind of change that must be explained. If, then, hylosystemism can explain this kind of change on the basis of a hylomeric constitution of bodies, it actually explains substantial change. All the objective evidence of science favors the hylomeric concept of change,

not the hylomorphic. Consequently, hylosystemism, not hylomorphism, must be accepted as the best explanation of the constitution and essence of inorganic bodies.

The battle between traditional hylomorphism and hylosystemism is on and will continue with increasing severity for a long time to come. Both theories have strong and weak points. It would be neither wise nor fair to treat either theory lightly.

A number of fundamental systems of thought have now passed in review; monadism, dynamism proper, energism, electronism; mechanical atomism, dynamic atomism, aetherism, hylozoism; hylomorphism; and hylosystemism. Of all these systems of thought, which attempt to give an adequate interpretation of the essential constitution of natural bodies, two stand out as having the greatest claim to truth: hylomorphism and hylosystemism.

This closes our investigation into the nature of individual bodies. We now turn our attention to the universe of bodies.

SUMMARY OF CHAPTER XIV

As an explanation of the essential constitution of inorganic bodies, hylosystemism stands in opposition to hylomorphism.

1. *Preliminary Observations.* There is a technical, a substance-and-accident, and a substantial hylomorphism. While the aristotelian-thomistic and the modern scientific concepts of the elements differ in secondary respects, they agree in fundamentals.

2. *The Crucial Problem.* The single point at issue and the common subject of discussion between hylomorphism and hylosystemism is the essence of inorganic bodies, the *ultimate constitution of inorganic bodily substances*, namely, of the elements and chemical compounds as such.

3. *The two theories.* Hylomorphism views the body as a composite substance consisting of primary matter and a substantial form. Hylosystemism views it as an atomary energy system working as a functional unit. *First difference.* In hylomorphism, elements and compounds consist of two incomplete substantial parts, matter and form. In hylosystemism, the constitution of bodies is hylomeric, i.e., it consists of heterogeneous matter-particles. *Second difference.* Hylomorphism rests upon a dualistic or binary conception of the body; hylosystemism, upon a pluralistic conception. *Third difference.* In hylomorphism the essential parts are incomplete substances; in hylosystemism these parts are complete corporeal or material substances. *Fourth difference.* Hylomorphic composition brings about

complete homogeneity in the substance; hylomeric composition, a heterogeneity of parts in varying degrees of coordination and subordination. *Fifth difference.* Matter and form interpenetrate; the hylomeric particles are spaced at a distance from another. Hence, the hylomorphic body is a unitary substance, while the hylomeric body is a system of corporeal or material substances.

4. *Hylomeric Constitution.* Hylosystemists claim that a hylomeric constitution is a *real essential constitution*. The parts form a whole which is more than the mere sum of the parts. It is natural, because brought about by natural tendencies. The parts are the intrinsic cause of the whole. These parts are substantial parts. They give to a body its specific essence.

5. *Hylosystemism Versus Hylomorphism.* The hylosystemists claim that the data of science demand a hylomeric constitution.

Concerning *minimal parts*. There is a definite limit to the division of bodies, and the minimal parts have a determinate size and mass; they also differ in size and weight. There is no principle in hylomorphism which can account for this, because a hylomorphic body is homogeneous throughout. The hylomeric constitution, which maintains a system of heterogeneous hylonic particles, readily explains all this.

Concerning *substantial change*. According to Aristotelian-thomistic hylomorphism, when a body undergoes substantial change, nothing changes but the specific form. According to hylosystemism, more remains in substantial change than primary matter and more changes

than the substantial form. When atoms break down, the hylonic particles remain. When compounds are formed or destroyed, there is always a change of system, matter, and energy. Again, according to hylomorphism, only forces extraneous to the body itself can inaugurate a substantial change. This is contrary to fact: the radioactive elements change spontaneously, and no outside force can influence the change. This is due to the complexity of the many hylomeric particles present in these elements.

6. *Modern Scholastics*. Many modern scholastics find a grave difficulty in reconciling the nuclear atom with the aristotelian-thomistic single form. Electrons and protons are space-separated individual particles, and the material form cannot exist except in matter. Hence, it seems impossible for one form to inform all the parts of the atom at once.

The advocates of hylomorphism, on their part, are convinced that the very unity of the atomic system demands a dirigitive principle of unity; otherwise the atom is but an *accidental aggregate*. This demands the form. Hylosystemists refer to the solar system as an example of such a unity through physical force, without the necessity of a form.

The essential difference between *electrons and protons*, hylomorphists claim, demands a hylomorphic constitution. Hylosystemists answer that this may be so, but it is here a question of the constitution of atoms and molecules as natural bodies, not of sub-corporeal particles.

Hylomorphists contend that no real *substantial change* can occur in a hylomeric constitution. Hylosystemists assert

that the change to be explained is the sort of change that occurs in nature, when elements unite into compounds and compounds are resolved into elements; and this sort of change, according to the evidence of science, is hylomeric, not hylomorphic.

PART IV

THE UNIVERSE OF BODIES

Chapter 15

HEAVEN AND EARTH

THERE ARE, AS WE HAVE SEEN, VARIOUS *LEVELS OF MATTER* among bodies. On the *subatomic* level we find, so far as our knowledge goes, electrons, protons, and neutrons, etc., as the ultimate components of bodies. They influence one another through their inherent forces of electricity and magnetism. On the *atomic* level the subatomic particles combine into a system, a structural unit, in which the electric and magnetic forces are neutralized. Each single system is an atom, and there are about 92 fundamentally distinct types of such systems, the elements. Each atomic system is a reservoir of powerful chemical energies. Then we have the *molecular* level, in which atoms of the same kind or of different kinds combine into a higher unit of matter and energy. The manifold types of chemical compounds have their origin in these combinations. The next step is the *mass* level. Molecules form masses or molar bodies — gases, liquids, or solids. These are the bodies we perceive by means of our senses, and they are usually termed ‘physical’ bodies. The final level is the *cosmic* level. Masses of physical bodies unite to form the earth, the stars,

the nebulae, and the interstellar matter scattered throughout the universe.

Ultimately, therefore, the entire universe of ponderable matter consists of neutrons, protons, and electrons. It is the *universe of bodies* which we must now submit to an examination. This includes the earth, the solar system, and the stars.

THE EARTH

The earth is a huge globular mass of bodies. Its equatorial radius is 3963.34 miles, while its polar radius is 3949.99 miles.

The earth weighs approximately six billion trillion tons. Since an ounce of matter contains about a billion billion billion (10^{27}) electrons, we can, if we possess a vivid imagination, obtain a very faint picture of the immense number of particles required to build the earth. At the equator the circumference is about 25,000 miles, so that the earth's rotational speed at the equator is more than 1000 miles per hour. The speed of the earth in its orbit around the sun is 18.5 miles per second, or one ten thousandth that of light.

The earth has had a long and varied history. This is evident from the *physiography* and *geology* of its surface. The earth's crust consists of many layers of sedimentary rocks resting upon a foundation of igneous rocks. The superposition of such layers determines their origin and age. The entire formation can be studied by traveling from Bryce Canyon in Utah to the Grand Canyon in Colorado, or

from Minnesota to Mississippi. The maximum thickness for the sedimentary rocks in North America is about 259,000 ft., nearly 50 miles. Only a rough estimate of the time required for the deposition of such enormous quantities of rock material can be given, because of the variable factors which enter into the representative rate of deposition. The time estimated is at least 100,000,000 years. The same figure was given by Joly for the age of the ocean. He estimated the total amount of sodium in solution in the ocean as quadrillion tons. Sodium is dissolved from rocks and carried to the ocean by the streams. From the present rate of such carriage it would take that much time to produce the percentage of sodium found in the ocean. These are minimum figures, due to the fact that in the past ages cataclysmic upheavals on land and sea have lifted submerged regions above sea level, so that for long periods of time no sedimentation was possible.

Physicists have discovered an age calculator in the *radioactive disintegration time* of actinium, thorium, and uranium. It will be remembered that the disintegration time of these elements is always constant, unaffected by external agencies such as heat, cold, or pressure. The end product of these elements is stable lead. From their lead ratio and disintegration rate, physicists attempt to calculate the age of the rock in which these minerals are present. According to the estimate based on this method, the geologic age of the earth must be well over two billion years.

CHART SHOWING ERAS AND PERIODS AND DEVELOPMENT OF LIFE*

ERA	PERIODS	LIFE	BEGAN	LASTED	KNOWN MAXIMUM THICKNESS OF SEDIMENTARY ROCK IN N. AMERICA
CENOZOIC (recent life)	Quaternary } Recent Pleistocene	Age of Man	1 million years ago	still continues	61,400 ft.
	Tertiary } Pliocene Miocene Oligocene Eocene	Age of Mammals	60 million years ago	59 million years	
MESOZOIC (intermediate life)	ROCKY MOUNTAIN CONSTRUCTION		EROSION INTERVAL		86,600 ft.
	Cretaceous Comanchian Jurassic Triassic	Age of Reptiles	170 million years ago	110 million years	
PALEOZOIC (ancient life)	APPALACHIAN MT. CONSTRUCTION		EROSION INTERVAL		111,000 ft.
	Permian Pennsylvanian Mississippian	Age of Amphibians	500 million years ago	330 million years	
	Devonian Silurian	Age of Fishes			
	Ordovician Cambrian	Age of Invertebrates			
PROTEROZOIC (early life)	GRAND CANYON-KILLARNEY REVOLUTION		EROSION INTERVAL		Total 259,000 ft. (about 50 miles) since beginning of Cambrian period
		Age of Primitive Forms of Life	1,000 million years ago	500 million years	
ARCHEOZOIC (beginning life)	WORLD-WIDE MT. CONSTRUCTION		EROSION INTERVAL		
			1,850 + million years ago	850 + million years	

*Taken from *This Earth of Ours*, by Victor Allen (Bruce, 1939), p. 210.

The conclusion seems inevitable that the earth was at one time a *hot globe* of more or less igneous matter. After a long period of cooling, the hot vapors in the atmosphere were precipitated, oceans formed, and sedimentation occurred. *Life* began on earth at a relatively recent period of its astronomical development. In all probability some forms of primitive flora and fauna existed in the archeozoic era. Definite proof of their existence is found in the fossils of the proterozoic era. From that point on, plants and animals appear in a continuous line of increasing complexity of structural development, until life reached its highest form in man. Man himself appeared in the quaternary period, and the beginning of his history probably coincides with the second interglacial stage. A study of the rate of recession of

Niagara Falls places the retreat of the last ice sheet at about 25,000 years. If this is a true estimate, man's existence on the earth is of a considerably longer duration. One must remember, however, that such calculations are based to a great extent on present-day conditions and are, therefore, nothing more than approximations of a speculative character.

The earth, of course, is not an isolated astronomical body. It is a part of the solar system and must be considered in that relation.

THE SOLAR SYSTEM

The solar system consists of the Sun and of nine planets. The planets, in the order of their distance from the Sun, are: Mercury, Venus, Earth, Mars, Jupiter, Saturn, Uranus, Neptune, and Pluto. To these must be added the moons of the planets, planetoids, comets, and meteors.

The *Sun* is the controlling center of the system. It has a diameter 109 times, a volume 1,300,000 times, and a mass 332,000 times, that of the Earth. In fact, its mass is about 700 times the mass of all the planets combined. A few statistics concerning the Sun may not be amiss.

Mean diameter.....	864,000 miles
Mass.....	1.32×10^{25} pounds
Rotation period.....	25—34 days
Velocity at equator.....	2.5 miles per second
Average density.....	0.25 that of Earth
Temperature at surface...	6,0000 C.

Energy radiated..... 9.07×10^{25} cal./sec.
Gravity at surface.....28 times that of Earth

Most of the Sun's energy is radiated from the *photosphere*, the gaseous disk visible to the senses. Enormous quantities of gases, chiefly hydrogen, calcium, and helium, rise into space from the disk for hundreds of thousands of miles. Some of these *prominences* are quiescent, others eruptive; the former remain relatively unaltered for days and even months, while the latter shoot up from the surface with explosive suddenness at a rate of 100—200 miles per second. The *chromosphere*, consisting mainly of helium and hydrogen, is a scarlet-colored envelope or layer which surrounds the Sun to a depth of several thousand miles. Below the chromosphere is a *reversing layer* of denser gases. Above the chromosphere we can observe the *corona*, visible during a total eclipse, which extends from the surface to a distance of approximately 300,000 miles. Scientists have not been able to penetrate this atmosphere with their instruments. The interior of the Sun is closed to observation. No doubt, the heavier atoms are concentrated in this core. Inasmuch as 60 per cent of the terrestrial elements have been identified in the solar atmosphere by means of the spectroscope, it is fair to conclude that all elements are present in the Sun.

The *heat* generated by the Sun is enormous. Although the Earth receives less than one two-thousand-millionth part of the solar energy radiated into space, the energy flowing continuously to the Earth furnishes the staggering total of 126,000,000,000,000 horsepower to our globe. It is

estimated that the interior temperature of the Sun is something like 10,000,000° C. The source of this energy cannot be ordinary combustion; it must be the liberation of atomic energy.

The *planets* gyrate around the Sun in elliptical orbits in a counterclockwise motion. Generally speaking, they occupy positions in the same plane.

Mercury. It is closest to the Sun. Its mean distance from the Sun is 36,000,000 miles. Of all the planets, Mercury has the greatest velocity, ranging from 23 to 36 miles per second, and it completes its revolution around the Sun in 0.24 years. Due to its proximity to the Sun, this planet is difficult to observe. Lacking definite markings, the period of rotation on its axis, if any exists, cannot be definitely determined; but it is estimated by some astronomers to be about 88 days. Its diameter is 3000 miles. No atmosphere has been observed, and the temperature must be excessively high.

Venus. More than any other planet, Venus resembles Earth. Its mean distance from the Sun is 67,000,000 miles. It completes its revolution around the Sun in 0.615 years, i.e, in 225 days with an average velocity of 21.7 miles per second. Like Mercury, its position between Earth and the Sun makes observation difficult. This, however, is certain: Venus is completely en-shrouded by a dense layer of white clouds. Oxygen and water vapor seem to be absent in the upper levels of this atmosphere. The temperature difference between the bright and dark side of Venus ranges from 50° C to -30° C. In size, this planet is as large as Earth, its diameter being only about 200 miles less. Its

period of rotation is unknown, due to its uniform atmosphere which shows no markings.

The Earth. Our globe is situated at a mean distance of almost 93,000,000 miles from the Sun. Its period of rotation is 23 hours and 56 minutes. Earth has a satellite, the Moon. Its mean distance is 237,500 miles; its diameter is 2160 miles; its volume is one fiftieth, and its mass one eightieth, that of Earth. The Moon has no atmosphere. The difference between the maximum and minimum temperature is approximately 250° C.

Mars. The mean distance of Mars from the Sun is 141,000,000 miles. It completes its revolution 1.88 years, traveling at an average speed of 15 miles per second. Its diameter is 4200 miles, and it rotates on its axis once in 24 hours, 37 minutes, and 22.6 seconds. The angle between its equator and the ecliptic is the same as that of Earth (23 ½°). Hence, the climatic zones of Mars must be similar to our own; the seasons, however, are nearly twice as long on Mars. This planet has an atmosphere, but it is very thin; this plainly implies a mean temperature which is well below freezing point. Two satellites revolve around Mars: Phobos and Deimos. The former is about 10 to 15 miles in diameter, and is situated less than 4000 miles from the planet; the latter is about half the size of Phobos and is approximately 10,000 miles distant. Both satellites travel in an eastward direction.

Jupiter. Jupiter is by all odds the most majestic of the planets. Situated at a mean distance of 489,000,000 miles from the Sun, it consumes 11.86 years to complete its orbit. Though it has a diameter of 87,000 miles, it has a rotational

period of only 9 hours and 50—55 minutes. Its average velocity is 8.1 miles per second. Its mass is more than 300 times, while its volume is 1300 times, that of Earth. This planet is enveloped in a dense atmosphere of gas. There is very little change in the seasons, and the average temperature is about -130° C. Jupiter has nine moons, of which five range from 10 to 100 miles in diameter; the other four compare with our moon and the planet Mercury in size. The two outermost satellites revolve around Jupiter in a westward direction at a distance of 14,600,000 and 15,000,000 miles; the remaining seven travel eastward.

Saturn. Saturn is the most spectacular of the planets. It resembles Jupiter in size, being 72,000 miles in diameter. It revolves around the Sun in 29.5 years, at a mean distance of 886,000,000 miles, with an average speed of 6 miles per second. Its rotational period is only 10 hours and 14—38 minutes. Since its equator has an inclination of nearly 27° , Saturn has seasons, but the average temperature is naturally very low. The most conspicuous thing about Saturn is the system of rings which surround the planet in the plane of its equator. The outer ring is 11,000 miles wide; then comes a gap 2200 miles wide; the next ring is 18,000 miles wide, merging with a faint inner ring, the crepe ring. These rings consist of particles of matter very much of the nature of dust, for stars are visible behind them. These particles are probably the remnants of an exploded satellite. Saturn has nine satellites, situated outside the rings at various distances; the outermost moves in a westerly direction, the rest eastward.

Uranus. Twice as far away from the Sun as Saturn, this planet, having a diameter of about 32,000 miles, has a mean distance of 1,782,000,000 miles, and makes its complete circuit in 84 years at an average speed of 4.2 miles per second. It rotates on its own axis once in 10 hours and 40 minutes. Because of its distance and slow movement, it was not discovered until 1781; the previously mentioned planets were all known to the ancients. It has four satellites, traveling eastward in the direction of the planet's own motion, situated between 120,000 to 360,000 miles away. The apparent westward rotation of Uranus and its moon is due to the fact that the equator of this planet is nearly at right angles to the ecliptic.

Neptune. The discovery of this planet is one of the most brilliant achievements of astronomical mathematics. Great difficulties had been encountered in calculating the exact position of Uranus in its orbit; it persisted in departing materially from its time schedule at designated points. Astronomers became convinced that the gravitational influence of a still more distant planet was responsible for this seemingly erratic behavior. J. C. Adams, of England, and V. J. Leverrier, of France, independently of each other, calculated the position of the disturbing planet, and J. G. Halle, of Germany, using the data of Leverrier, discovered the planet in 1846 after a very brief search. Its mean distance from the Sun is 2,793,000,000 miles, and it travels with an average velocity of 3.4 miles per second to complete its revolution around the Sun in 164.8 years. Neptune has a diameter of about 33,000 miles, slightly larger than Uranus. Its period of rotation has not been

determined. One satellite, probably of the same size and distance as our own moon, revolves around the planet in a little less than six days.

Pluto. This planet was discovered in 1930. Its mean distance from the Sun is 3,670,000,000 miles; between its nearest and remotest point, from the standpoint of the Sun, the variation in its distance reaches the sum of 1,800,000,000 miles. It travels at a rate of 2.9 miles per second, and its period of revolution is 248 years. Its diameter is not known, nor the period of its daily rotation. Some astronomers are inclined to place Pluto in the category of planetoids, because of the eccentricity of its course.

Planetoids. Planetoids, or asteroids, are very small planets. The first was discovered in 1801 and was called Ceres. Its diameter is a mere 480 miles. Since that time the discovered planetoids number more than a thousand, most of which lie between the orbits of Mars and Jupiter. All move in an eastward direction, as do the planets. Two planetoids come very close to the earth. One, with a diameter of about 1 or 2 miles, approached within 10,000,000 miles, and another, of approximately the same size, was even as close as 6,500,000 miles. Both were discovered in 1932. The orbits of some planetoids are extremely eccentric.

Comets and Meteors. Comets usually consist of a fiery nucleus, which may be a few hundred miles in diameter, a nebulous glowing head, often larger than the Sun in diameter, and a streaming tail which, in some instances, extends over a distance of 100,000,000 miles across the

heavens. The number of comets which are a part of the solar system is very large, perhaps hundreds of thousands. Their period of revolution may be anywhere from a few years to thousands of years; the latter, of course, have orbits which extend far beyond the limits of the remotest planets. They move, with few exceptions, from west to east around the sun. It happens at times that the tidal action of the Sun breaks the nucleus of a comet apart; this happened to Biela's comet. In such a case the comet probably disintegrates into meteors.

Meteors, or 'shooting stars,' are small particles of matter, like grains of sand. When they strike the earth's atmosphere, the heat of friction makes them glow. They then disintegrate to dust. It is estimated that millions of meteors enter Earth's atmosphere daily. In some instances entire swarms travel together in a regular orbit; as the earth crosses their orbit, showers of meteors become visible. Such are the Bielids, Leonids, Lyrids, Perseids, and Giacobinids.

Meteorites are, in all probability, merely meteors of a larger size. Parts or fragments manage to reach the earth's crust. Some, the aerolites, consist of stone material (limestone, magnesia, or silicon), while others, the siderites, consist of metal (iron, alloyed with nickel, with small amounts of copper, cobalt, phosphorus, etc.). Occasionally, a meteorite, weighing many tons, falls to the Earth. A meteorite, which fell in Winslow, Arizona, made a crater a mile wide. Astronomers are convinced that some of these meteorites come from outside the solar system, remnants of exploded stars.

After this brief description of the solar system, we must turn our attention to the universe of stars.

THE UNIVERSE OF STARS

From the standpoint of terrestrial units of measurement, our solar system is spread out over an enormous area. Compared, however, with the rest of the universe, it is negligibly small. Nor is it an isolated system; it is merely one system in a veritable cloud of systems forming what is commonly known as the Milky Way. Our solar system as a unit moves with a velocity of 12 miles per second toward the constellation of Hercules.

The *constellations* are groups of stars joined together by imaginary lines, for the purpose of identification. So far as their actual position in the heavens is concerned, this grouping is purely fictitious, for they do not really belong to the same group or system as indicated by the constellations.

The *number of stars is definitely limited*. The number of observable stars has, of course, increased with the size and perfection of the telescope, but so has the area of starless space grown proportionately larger in extent. This is confirmed by the spectroscope. The total number of stars in all probability amounts to several billions.

By various ingenious methods astronomers have succeeded in measuring the distance, magnitude, composition, and luminosity of the stars. The *light-year* and the parsec are the standard units for measuring distances in the universe. A 'light-year' is the distance which light will

traverse in a year's time. Since light travels over 186,000 miles per second, it covers nearly 6,000,000,000,000 miles in a year. A 'parsec' is equivalent to 3.26 light-years. Proxima Centauri, the closest star which has been discovered, is 4.15 light-years or 1.27 parsecs away. Sirius is 8.6 light-years away, and some of the stars of first magnitude are as much as 400 light-years (Antares) and more than 500 light-years (Rigel, Canopus, Deneb) distant from the earth. When we realize that it takes only 8 minutes for light to travel the more than 92,000,000 miles from the sun to the earth, we have a fair estimate of the distance between the earth and these stars. These stars are relatively close, when compared to the extent of the universe as a whole. Though the calculations of astronomers are of necessity only approximations, we may assume that they are substantially correct.

It must be borne in mind that each star is not really 'fixed' or stationary; it has its own proper motion. This, of course, differs with the different stars. For example, Halley in 1718 noted that, since Ptolemy's time, Sirius had moved $\frac{1}{2}^\circ$, and Arcturus 1° , southward. Due to the long time it takes for the light of stars to reach the earth, one result of their proper motion is that none of them are in the actual position where we see them in the skies. The entire picture of the starry heavens is, therefore, actually quite different from the one which appears to our senses.

Astronomers distinguish between *dwarf* stars and *giant* stars.

'Giants' are known for their great absolute luminosity, some being thousands of times more brilliant than the sun,

while 'dwarfs' have a low luminosity, in some instances being no more than $1/10,000$ that of the sun. Indirect and direct evidence shows that the difference in luminosity must be due to their size. Antares, for example, has a volume which is about 70,000,000 greater than the volume of the sun, because its total radiation is 3000 greater, although its rate of radiation per unit area is only about one fiftieth that of the sun. Sirius is a *binary* star, a double star, one a giant and the other a dwarf. The two are nearly a billion miles apart, and it takes 48.8 years for them to complete their revolution. The dwarf's diameter is only $1/30$ that of the sun, while the combined mass of both is 3.4 times that of the sun. There are many such combinations in the heavens. According to all indications, the dwarfs greatly outnumber the giants among the stars.

The density of the giant stars is low, while that of the dwarf stars is extremely high. It would seem but natural that some of the giants might eventually collapse, while reversely, the dwarfs might expand with explosive force. Actually, astronomers know of stars which suddenly flare up and increase enormously in luminosity and size. There are the so-called *novae* or 'new stars.' To mention but a few of recent date:

Nova Persei (1901), Nova Aquilae (1918), Nova Pictoris (1925), Nova Herculis (1934). The explosion is at times very sudden; thus, Nova Aquilae within two days, from a star of eleventh magnitude, became a star of first magnitude. At other times, the change extends over months and even years. Later, the novae seem to subside to a more or less normal condition, but there are indications that some

undergo great change: for example, it is claimed that Nova Herculis split into two separate stars after its phenomenal burst of fiery expansion. Some stars seem to expand and contract in definite periods.

Quite different from the stars are the *nebulae*. They are immense clouds of gaseous matter spread out through interstellar space. So far as their density is concerned, they are of extreme tenuity. The dimensions of some nebulae stagger the imagination. The Great Nebula in Orion, for example, is so vast in extent, that it is visible to the unaided eye, although it is 600 light-years away; its breadth is estimated at 10 light-years. Some nebulae are luminous, others are dark. Astronomers find the reason for the luminosity of the former in the proximity of stars which supply them with light; the dark nebulae have no stars near by and therefore lack illumination.

One of the most interesting spectacles in the sky is the *Milky Way*. It consists entirely of stars. From the standpoint of the terrestrial observer, it would seem that the stars are massed here in greatest concentration. This, however, astronomers assure us, is not the case. There is actually no crowding of stars. The fact is that the assemblage of stars is distributed in such a manner that the whole galaxy forms a sort of flattened disk. We are merely looking through the galaxy down its longer axis toward its outside border; that gives the appearance of greater concentration. Our view of the heavens may be compared to looking through a low fog; it seems thin when we glance upward in a vertical direction, but thick when we look into it lengthwise in a horizontal direction. It is estimated that the Milky Way is about 30,000

light-years wide on its long axis and about 3000 light-years on its short axis. Thousands of millions of stars comprise this galaxy. They are, of course, not equidistant apart; rather, the galaxy is made up of huge clusters of stars, interspersed with nebulae, and in this sense there exists a partial concentration.

Besides the Milky Way, we notice great *globular clusters* of stars. They are not, in the ordinary meaning of the term, a part of the Milky Way, for they are situated from 20,000 to 200,000 light-years off to the side. Astronomers recognize nearly a hundred such globular clusters. Some of them number their stars by the millions, so that, because of their tremendous distances, they resemble nebulae rather than clusters of stars; such is the Great Spiral Nebula of Andromeda, it being nearly a million light-years away and possessing a maximum diameter of about 42,000 light-years. Some astronomers are of the opinion that practically all these galaxies should be considered as parts of a vast single system. If this view is correct, then the universe of stars would have a maximum diameter of approximately 250,000 light-years and a thickness of approximately 35,000 light-years, with its center in the direction of Sagittarius. The globular clusters would then mark the outer border of the whole system. It might very well be that many galaxies exist which are still beyond the reach of our most powerful telescopes, millions and hundreds of millions of light-years out in space. There seems to be a veritable universe of spirals which are galaxies of stars similar to the Great Spiral Nebula of Andromeda, too distant to be discernible as such.

DIMENSIONS OF THE UNIVERSE

From time immemorial, man has speculated as to the extent of the universe. Is the world *finite* or *infinite* in its dimensions? Modern astronomy, in its estimates of distances among stars, speaks of thousands and millions of light-years; and with the increasing perfection of its instrumentalities of observation, the confines of the physical universe seem to recede farther and farther into practically illimitable distance. Has then, the universe limits? Or, is it limitless in its tri-dimensional expanse?

As for *science* itself, it has not discovered the limits of the universe, if such limits there be. It is true, of course, that astronomers assign definite limits to the dimensions of the Great Galaxy of the Milky Way and adjacent galaxies. It must be remembered, however, that certain celestial bodies which, because of their incalculable distance, appear as single stars or at most as minor nebulae, may in reality be galaxies comparable to the Milky Way itself. And what lies beyond these, no one can say. The imagination stands stunned before the possibilities which it contemplates. Science offers no factual, positive evidence to prove that the universe is limited in extent; conversely, it cannot show that it is limitless in expanse.

Some argue against the infinitude of the world on the ground that this would postulate an *infinite number of stars*, and that, in turn, would mean an infinite amount of light being radiated; but in that case the heavens at night would be covered with a 'blanket of light.' The argument, however, is hardly valid. For one thing, we can only see light

or a star, after the light reaches the earth. Unless the argument also includes an infinite time for the universe, much of the light may not have reached our earth up to the present time. Again, much of this light might have been absorbed by the cosmic dust existing in space between the stars, so that the light never reaches us. Furthermore, light, being a form of energy, might be so weakened and dissipated on its long journey, that it is either stopped entirely or is too weak to make an impression on our senses. Most of all, however, the argument fails to convince, because an infinite extent of the universe does not necessarily involve the postulate of an infinite number of stars. The nebulae are not stars. The stars occupy but a small portion of the space of the physical universe. The universe, therefore, could extend far beyond the range of the stars and consist of gases or even aether. In that event, however, there would exist but a finite number of stars with a finite amount of light, and then the skies would not show an uninterrupted 'blanket of light.' Taking these objections into consideration, we must reject this argument which purports to prove the limited extent of the universe for scientific reasons. Science, in its present stage of development, seems unable to prove or disprove the infinitude of cosmic dimensions.

Philosophy seems in a better position to solve the problem. Philosophers have held different views on the subject. *Anaximander* accepts the 'unlimited' as a basic principle of his philosophy of nature, and this 'unlimited' is equivalent to an infinite material substance. *Democritus*, *Epicurus*, *Lucretius*, and the ancient atomists generally,

assume an infinite number of atoms in an unlimited space. The *stoics* believed in an infinite space, but considered the world itself to be finite; *Plato* taught a similar doctrine. *Aristotle* defended a finite universe, but maintained its eternity. The medieval scholastics viewed the world as limited in extent. Modern philosophers and scientists, whenever they express themselves on the subject, generally concede that the universe should be considered as limited. There are, however, some exceptions. *Giordano Bruno* (1548—1600), in consequence of his naturalistic pantheism, defended the infinity of the world. Some materialists, for example, *Buchner* and *Haeckel*, considered the universe to be infinite and eternal. Kant viewed the question as meaningless, because the world is a noumenon, a thing-in-itself, while space is a phenomenon, a purely subjective innate sense form; hence, we cannot acquire any knowledge of the physical universe as it exists for itself.

Before attacking the problem, it will be necessary to clarify the question. Much confusion will be avoided, if the concepts of indefinite dimensions and infinite dimensions are clearly understood and held apart. By 'indefinite dimensions' we understand dimensions which have limits, but these limits cannot be strictly assigned either as to location or number of measuring units or both. It can be readily granted that the dimensions of the universe, in this sense, are 'indefinite.' We do not know exactly where the universe ends nor can we indicate the number of light-years of distance from one end of the universe to the other in any direction. This is due to our limits of observation. By 'infinite dimensions' something very different is meant. It means

that the universe has no limits in any direction; or, it means that there are no limits in one direction, length or breadth or height. Infinity in one direction only is a mathematical fiction. An actual body or assemblage of bodies in three dimensions, in order to be limitless in extent, must be limitless or infinite in all directions; otherwise its dimensions would really be limited and not infinite. Hence, in this question 'infinite dimensions' coincides with 'tri-dimensional infinitude.' Practically speaking, this implies that the measuring units applied to the universe in any and all directions can be repeated without end, an infinite number of times, not merely an indefinite number of times. It implies that no amount divided into the total, or subtracted from the total, can ever exhaust the total without a remainder. Hence, whether we use as our yardstick of measurement the meter, the mile, the light-year, or a million or quintillion light-years, or any other unit, this yardstick could never reach the limits of the universe even in an eternity or infinity of applications, for the simple reason that the universe has no limits in its extension. Furthermore, since the universe consists of individual bodies which can be numbered, 'infinite dimensions' imply an infinite number of bodies, so that in their aggregate their individual dimensions will sum up to an infinite extension in three dimensions for the universe as a whole. Any other supposition would amount to 'indefinite dimensions,' but not to 'infinite dimensions.'

As will have been noted, the question of the 'infinite dimensions' of the universe resolves itself into the question of an *infinite number of bodies* and also into an *infinite*

number of units of measurement contained within its dimensions. For anyone who is convinced that an infinite number is intrinsically impossible, because it involves a contradiction in terms, the question is already settled: the universe must be limited in extent. However, leaving this *a priori* argument aside, a consideration of our universe as a physical reality leads us to the same conclusion.

An infinite number can neither be increased nor decreased. If it could be increased, it would, by that very fact, show itself to be limited and not infinite. If it could be decreased, the portion deducted would certainly be limited; and the remainder would also be limited, because it could again be increased by the deducted portion. It follows, then, that an infinite number can neither be increased nor decreased; it cannot, therefore, consist of a mere addition of limited numbers, each of which can be exhausted by division or subtraction. If each single part of a total is finite, so that its dimensions can be exhausted through numbering and measuring, through division and subtraction, then the total itself is limited and finite. After these preliminary observations, let us consider the facts pertinent to the problem.

In physical nature, the dimensions of a body become manifested in their *size*. Every physical substance or body, existing in the universe, possesses a *measurable size*, a definite *volume*, a geometrically definable *shape*. This applies to electrons, protons, atoms, molecules, masses, meteors, comets, planets, and stars. Gases and liquids consist of definite quantities of molecules, whether they are confined in jars or oceans, whether on earth, in a star, or

dispersed through interstellar space. That man, with his limited means and instrumentalities, cannot assign precise measurements to these realities, is beside the question. *In themselves*, these bodies and substances have *limited dimensions*. But the whole universe consists of such bodies and substances. Therefore, the whole universe is limited in its dimensions.

Let us look at the problem from another angle. The number of *celestial bodies* in the universe is obviously limited, not infinite. The stars, planets, planetoids, comets, and meteors occupy but an extremely small place in the total universe. There could be many more such celestial bodies than those which actually exist. The number of *electrons, protons, atoms, and molecules is not infinite, but limited*. This is seen from the fact that the interstellar spaces are relatively empty of material substances. Wherever the elements, such as hydrogen, calcium, sodium, etc., are found to be present, they are so tenuous that the highest vacuum man can produce artificially contains a more concentrated amount of such elements than astronomers estimate are found in an equal area of interstellar space. This space cannot be packed solid with elements, otherwise the motion of planets and stars would be impossible; we find, however, that these celestial bodies are not noticeably retarded through friction. Besides, if our modern concept of the atom is correct, all atoms are, for the greatest portion of their volume, empty of material substances. There can be no doubt, then, that the number of material particles (electrons, protons, atoms, etc.) in the universe *could be larger*. To put it practically, God could

create a far greater number of individual particles of matter in the universe than now exist. A number, however, which can be increased, is not an infinite number. Hence, the universe consists of only a limited, though indefinite, number of bodies, and this number can be exhausted without a remainder by division or subtraction. Consequently, the *physical* universe is not infinite in its dimensions.

But how about the *aether*: Could that not extend without limit? We know so little about the aether, that it seems presumptuous to argue one way or the other. However, if we may assume that the law of impenetrability applies also to the aether, since it is a material though imponderable substance, then we must assert that the amount of aether existing in our universe is also limited. The argument runs as follows. The aether does not occupy all possible space, because it does not occupy the space in which the ponderable matter (electrons, protons, etc.) is found. Inasmuch as this space could be filled with aether instead of with ponderable matter, the amount of aether could, absolutely speaking, be greater than it actually is. Hence, the amount of aether, since it could be increased, is in itself a limited amount. But that means that the aether is not infinite in extent. Now, if all ponderable matter and all imponderable matter in the universe is limited in amount, the whole universe consists of a limited amount of matter. But a limited amount of matter can be measured out through division and subtraction, because a limited amount of discrete entities involves a limited number of such entities. One might object, that the *sum* of both might add

up to infinite dimensions, even though the single ones do not. The objection is invalid. If ponderable matter is limited, it can be exhausted by measurement; and if imponderable matter is limited, it also can be exhausted by measurement. Since both can be exhausted singly by measurement, it is obvious that the summation of both makes no real difference: the total amount can be exhausted by measurement. But the total amount of ponderable and imponderable matter constitutes our entire universe. Hence, our entire universe is limited in the total amount of its matter and must, therefore, be finite in its dimensions, because the dimensions of its constituent parts are finite: an aggregate cannot be more than the sum total of its parts.

We must conclude, therefore, that our universe is indefinite, but not actually infinite, in its dimensions. By the very fact that our universe is actually finite, it follows that more bodies and more matter, speaking absolutely again, could be added to the amount existing; in other words, God can extend the present limits of the universe by creating more material, and this indefinitely, because a finite number can never become actually infinite by the mere addition of more finite numbers: the sum will still remain finite.

The final conclusion, therefore, must be: our universe is, and always will be *actually finite*; but inasmuch as it can always be increased indefinitely, it is *potentially infinite*.

THE PLURALITY OF WORLDS

The question has often been raised: *How many* universes are there? Only one? Two or more? In a way, the question seems pointless. However, the question possesses speculative value. Can we arrive at any decisive answer to the question?

In order that the question have an intelligible meaning, we must be clear in our minds just what is meant by a *plurality of worlds*. If there are single bodies or systems of bodies which are totally out of contact with our own universe, so that absolutely no interaction of any kind exists between them, then these bodies or systems form a different world or universe for themselves and cannot under any circumstances be adjudged as forming a unit with our own. If so, then we have a plurality of universes. But if a cosmic bridge exists between them, so that the one can influence the other in any manner whatever, then the mere fact of their cosmic union would make them integral parts of a higher unity or system. In that case, they should not be looked upon as a plurality of worlds. In order to speak of a 'plurality' in this connection, both or all must be absolutely *independent and autonomous*.

There can be no serious question about the possibility of a plurality of universes. Only under the supposition that our own universe be infinite in dimensions, so that it would fill out all possible (absolute) space, could there be any cogent reason advanced against the possibility of more worlds than the present universe in which we live. Our own universe, as we have seen, is limited in extent, not infinite. Hence, other worlds could exist outside the boundaries of our own. And this is true, whether we accept the creation of our universe

in time or its existence from eternity. If we accept creation, no valid reason can be given, why God could not create other worlds beside our own. His power, being infinite, could not be exhausted through the creation of our universe, since our universe is finite. His wisdom, being infinite, could certainly devise similar or different universes and have grounds for creating them, as He did our own. If we accept (for the sake of argument) the eternal existence of our universe, the eternal existence of another world or other worlds, as a possibility at least, must be accepted, because under such a supposition no cause operated to give existence to one world in preference to others. Hence, a plurality of universes is, from the standpoint of reason, at least possible.

Can we know whether other worlds *actually exist*? With the aid of human reason alone, we are incapable of knowing whether other worlds actually exist. Such worlds would be shut off completely from our empirical knowledge. Knowledge could be acquired only by observation of some sort, and that would demand a *medium of communication* between our world and these others, either through light or electricity or gravitation or some other means of interaction. But such a connection would presuppose a cosmic bridge, a contact of entity and operation, which would destroy their independence and autonomy as separate and separated cosmic units; and thereby the plurality of worlds, as postulated, would give way to a single universe on a larger scale. Our senses are irretrievably bound to the beings and bodies of our own universe; what lies beyond can never be observed. For that reason, too, we

cannot deduce the existence of other worlds by means of a process of reasoning from the data of our present universe. Other worlds, being totally disconnected from our own, may be of an entirely different constitution, so that the realities and laws pertaining to our universe have no application in another world. We *cannot even imagine* what such a universe would be like, because all our images are derived from our sense impressions of this world. We have no means of bridging the gap between our universe and any others which might possibly exist.

What would happen, if a star or comet or meteor reached the boundary of our universe? Would it stop? Or, would it continue in its motion beyond the boundary? The question is interesting, but it can hardly be answered. Can any body escape the gravitational attraction of the whole universe? It would seem not. If not, then it should stop at the outermost limits of our universe. On the other hand, since a body will move in the same direction without stopping, unless acted on by an outside force (and there is no such force here), should it not continue indefinitely in the forward direction of its motion and sweep out into empty space? This, too, seems probable. But in what direction would it be going, since there are no directions in empty space? And again, do not the Newtonian Laws of Motion merely apply within the confines of our universe? And where would it go, once it left our world? There are, apparently, no places to which its motion could possibly carry it. It seems more logical to suppose that all bodies within our universe are confined to our universe and can never leave it. But this is only a supposition.

How far away from our universe would other universes be, provided there were such? Absolute or empty space, as we conceive it, is an imaginary thing; it is not an actual reality; it is the mere possibility of other bodies. And since only bodies can be measured, using one type of body as a measuring unit for others, absolute or empty space admits of no measuring units and cannot, therefore, be measured. Hence, there are no distances, in any real sense of the term, in absolute space. It is a pointless question, consequently, to ask how far other worlds would be distant from our own. Absolute space being in reality nothing, we cannot speak of length or breadth or height, of right or left, of up or down, of far or near, of a meter or a mile or a light-year; these concepts have no application and meaning in complete emptiness. The various worlds, if they exist, are simply not in contact, and each is confined within the limits of its own boundaries.

Our knowledge about the plurality of worlds is thus seen to be almost entirely of a negative character. We cannot know whether or not they exist; and if they exist, we can know nothing about them. Our reason, unaided by revelation (and revelation is silent on the question), is certain of only one thing: A plurality of worlds is possible. More than that we cannot deduce, for to argue from possibility to actuality would be an illogical inference.

OTHER INHABITANTS

More than the problem of a plurality of worlds, the question of *other organisms and rational beings* on stars and planets

has agitated the minds of scientists and philosophers.

In discussing a problem of this sort, it is necessary to specify the *type* of living beings one imagines to exist on these stars or planets. If we consider the very high temperatures of the sun and of the glowing stars, it is obvious that organisms of the types with which we are acquainted on our earth could not survive; the liquids of the protoplasm would evaporate, the carbons of the cell structure would burn, and the entire organism would crumble into dust. A temperature of a few thousand degrees, as we know from experience, will destroy any organism on earth. Such beings are, therefore, excluded from the hot stars. Similarly, an extremely low temperature will effectually kill any organism known to us. Hence, any planet or star, whose temperature is permanently below -100° C., could not support life of a terrestrial type. This would, in all probability, rule out the planets which are far away from the sun, namely Jupiter, Saturn, Uranus, Neptune, and Pluto. Mercury and Venus are excluded, because, being so near the sun, their temperatures are too high; besides, no atmosphere has been observed on Mercury, and the atmosphere of Venus seems devoid of oxygen and water vapor, and these are essential to life for the organisms we know. Of course, anyone who wishes may imagine organisms which could live in a flaming star or on a frozen planet; such speculations, however, are the play of sheer fancy and have no objective value. If the problem is to have a reasonable foundation, the discussion must be restricted to organisms which are similar to those of which we have some knowledge.

There can, it is true, be no valid reason for denying the *possibility of other types* of beings on such stars and planets. The conditions on them being very different from those on our earth, such beings would be adapted to these conditions. But we have no way of knowing what the structures of such beings would be like. Hence, it would be an idle dream to even take such beings into consideration. The only sensible procedure open to us, is to limit the question to creatures identical or similar to those existing on our planet. That other planets or stars, with conditions similar to the conditions of our earth, might possibly exist somewhere in the universe, is also true. However, if they exist, they are unknown to us — with one exception. This exception is the planet Mars.

Mars, in many respects, compares favorably with the earth. It is about the same size, its day is about as long, its angle of inclination is similar. Because its year is almost twice as long as that of the earth its seasons are also twice as long. And it also has an atmosphere. There are, however, also unfavorable conditions. The atmosphere of Mars is very thin. Its mean temperature is most likely well below freezing point. Many of the organisms which live on this earth could not live on Mars. Man, with his capability of adapting himself to climatic conditions, might possibly be able to survive on Mars, provided he could live in its tenuous atmosphere; scientists are very skeptical about this.

Schiaparelli, in 1877, claimed to have observed what he called 'canals' on Mars. These markings or streaks, which are narrow and dark, are supposed to follow the arcs of

great circles and are hundreds and thousands of miles in length. *Percival Lowell* improved on Schiaparelli's idea by maintaining that these canals form parallel circles around the globe of Mars and are intersected by other canals, so that a complete network of canals, over 400, covers the entire surface. He supposes that living conditions for the Martian inhabitants are extremely difficult, making it necessary for them to drain the polar caps by means of these canals, in order to obtain water for vegetation. These markings, therefore, represent vegetation. Most astronomers are of the opinion that Lowell let his imagination run wild, because very diligent search and study have failed to reveal anything which resembles such a definite system of canals. Perhaps larger and better telescopes will settle this question in the near future. If these markings are really canals, they are of tremendous length and breadth, which fact alone renders their existence doubtful. Due to the conditions on Mars, some fanciful writers imagine the supposed inhabitants to be some sort of supermen. The whole question has entered into the realms of the fantastic. The bald facts of the case are these: While the conditions of Mars could undoubtedly support some forms of life, there is no positive evidence that organisms exist. Much less is there any evidence that intelligent beings have their abode on this planet. Hence, we are not certain that life is present on Mars.

Some Christian philosophers have attempted to prove the existence of *rational creatures* on other stars or planets on the grounds that it seems unreasonable to suppose that the earth alone has intelligent beings. The wisdom and

goodness of God apparently demands the existence of such beings besides man in other parts of the universe, in order that the works of God and thereby the power and wisdom of God Himself, be recognized and duly appreciated. The argument lacks cogency. If we stress the argument, then it seems unintelligible why man himself should have appeared so late on the scene, measured in terms of the history of the universe, and why, now that he is here, he understands so comparatively little about even the simplest realities, not to speak of the great riddles of the universe. Here again, though, we must say that it is *possible* that other rational beings, perhaps with an intelligence far superior to that of man, actually exist somewhere. They could be of an entirely different order, so that we would never be capable of observing their presence here on earth or anywhere else. That, however, is pure speculation and can lead to no practical result. So far as man can judge by observation, there is no sound evidence for assuming the existence of life, as we know it, anywhere but on the earth.

Some persons are pleased to make a disparaging comparison between 'puny man' and the 'immeasurable universe.' They liken him to a worm crawling on a grain of sand floating through immensity. The universe is indeed a gorgeous phenomenon, terrifying in its magnitude and magnificence. The greatness of man, however, consists in the fact that, though a physically insignificant entity amid all this cosmic vastness, he possesses reason and, with reason, the ability to interpret the world. In this he surpasses the universe, for that makes him akin to God.

SUMMARY OF CHAPTER XV

The various levels of matter lead us to a consideration of the universe of bodies.

1. *The Earth.* From the physiography and geology of the earth's surface we see that the earth's crust consists of many layers of sedimentary rocks resting upon a foundation of igneous rocks. It is estimated that it required at least 100,000,000 years for the sedimentary rocks to be laid down. The earth must have been at one time a hot globe of igneous matter.

Life is a comparatively recent phenomenon, and man is the most recent of the organisms, having probably appeared in the second interglacial stage of the quaternary period.

2. *The Solar System.* It consists of the Sun and nine planets: Mercury, Venus, Earth, Mars, Jupiter, Saturn, Uranus, Neptune, and Pluto. To these must be added the moons of the planets, planetoids, comets, and meteors. The mean distance of Mercury, the planet nearest the Sun, is 36,000,000 miles, while that of Pluto, the most remote, is about 3,670,000,000 miles; the Earth is over 92,000,000 miles distant from the sun.

3. *The Universe of Stars.* The number of stars, though limited, amounts to several billions. Proxima Centauri, the closest star known, is 4.15 light-years away. There are 'giants' and 'dwarfs' among the stars. Some stars are 'novae' which suddenly flare up and increase enormously in luminosity and size. Nebulae are immense clouds of

gaseous matter. The Great Galaxy of the Milky Way, of which our solar system is a part, consists of billions of stars; it is estimated to be about 30,000 light-years wide on its long axis and about 3000 light-years on its short axis. There are also great star clusters off to the side of the Milky Way, situated at a distance of from 20,000 to 200,000 light-years. They may possibly form one great system with the Milky Way, approximately 250,000 light-years in diameter.

4. *Dimensions of the Universe.* Is the universe finite or infinite in extent? Science cannot answer the question. We must distinguish between 'indefinite dimensions' and 'infinite dimensions.' To be of infinite dimensions, the extent of the universe in all directions must be such that the measuring units can be repeated without end, an infinite number of times, without ever exhausting the total. This implies an infinite number of individual bodies and of units of measurement.

The universe is *limited*. The amount of ponderable matter is limited, since the interstellar spaces are relatively empty; more ponderable matter could find place. The same applies to *imponderable* matter (aether) because the amount of aether would be increased if it occupied the place of ponderable matter. Since both the ponderable and the imponderable matter is limited, the whole matter of the universe is limited in amount and can be measured out. But an infinite quantity cannot be measured out. Consequently, the universe is finite, not infinite.

5. *The Plurality of Worlds.* By a plurality of worlds we understand two or more universes existing simultaneously, totally unconnected, independent and autonomous. Our

universe being finite in extent, no valid ground can be advanced, why a plurality of worlds should not be *possible*. But we could know nothing of their existence or structure, because there would be no medium of communication between our universe and them.

6. *Other Inhabitants*. In the problem, whether other organisms or intelligent creatures exist somewhere in our universe, we must restrict the question to beings similar to those on our earth; we otherwise enter the realm of fancy. The hot stars and the extremely cold planets are incapable of supporting life of this kind. Mars has conditions somewhat similar to those on our earth; but its atmosphere is very thin, and its mean temperature is well below the freezing point. The so-called canals are very dubious evidence for the existence of intelligent beings. Other inhabitants are *possible*; but there is no evidence based on observation which would indicate their presence in our universe.

Chapter 16

THE COSMOS

SCIENCE, BY PAINSTAKING AND PATIENT OBSERVATION, experiment, and analysis, has solved many of the mysteries of nature. By means of the spectroscope, the telescope, and other instruments, man has been able to reach far out into the vast expanse of the universe. The ptolemaic conception of a geocentric world of spheres had to give way to the copernican conception of a gigantic super-system of the universe in which the heliocentric system plays but a small part. The celestial bodies instead of being composed of the uniform and incorruptible element aether, as Aristotle taught, are now known to consist of the same elements as are found everywhere on this earth. Spirit beings no longer guide the stars and the spheres in their perennial circular motion; rather, physical forces direct the movement of all the bodies in the heavens in an amazing and intricate pattern. The stars are so multitudinous, so enormous, and so vast in their distances, that man's mind feels numbed before all this bigness and finds difficulty in its attempt to find a cosmos instead of a chaos.

Is the world really a *cosmos*? Or, is it only a *chaos*? Is it really an ordered whole? Or, is it merely a jumbled

aggregate? This is an important question, and it clamors for an answer.

UNITY IN THE UNIVERSE

When we speak of the world as a cosmos, we signify that it is an *orderly system*, namely, an assemblage of diverse units so combined as to constitute an integral whole and to function in unison in obedience to some form of control. It is essential to the concept of a cosmos that its parts be interrelated, inter-dependent, and interacting in such a manner that, notwithstanding the diversity of the single objects as units in themselves, they conspire toward an assemblage of all together as a unit or totality of a higher order. Because of the immensity of the universe, both in the number of its component parts and in the distances which separate them, it will obviously be difficult to trace the functioning of the system as a whole except in broad outlines; it is utterly impossible to do this in minute details. However, it is the general conviction of reliable scientists, that such a system prevails and that the world is really a cosmos. There is every indication that the entire universe consists ultimately of the *same uniform elements*. It is, of course, possible that some elements exist in the stars of which we have no knowledge here on earth. Helium, for example, was discovered in the sun before it was found on earth. Since our radioactive elements, at the end of the Periodic Table, form a short series, it is possible, and perhaps even likely, that they are derived from heavier elements, and these elements may exist in their original

condition on some star or in some flaming sun. Be this as it may, it would still be true that the composition of all bodies is made up of the same uniform elements. The number of elements, whether 92 or more, is of minor importance and does not affect the cogency of the general argument. The fact, however, that all bodies in the world, so far as is known, are built up from the same, relatively few elements, is in itself a very strong argument that the world is arranged in the unity of a cosmos. This argument receives strong confirmation from an examination of the single types of elements and the structure of the atoms of which they are composed.

Leaving aside the philosophical question of the ultimate constitution of elements, and viewing them solely from the scientific standpoint, we distinguish the different *types of elements* according to the different *types of structural atoms*. And here the striking fact comes into prominence, that all atoms of all elements are the combination of a few fundamental constituents. And since the same elements exist in the bodies throughout the universe, the composition of the whole universe is based, as we rightly conclude, on these same types. The universe, therefore, possesses a *constitutional unity* which alone would be sufficient to demonstrate that the world as a whole is a 'system.'

While the *systematic arrangement* of the world at large is not so obvious, that of the individual atoms is clear — provided, of course, that the modern interpretation of the atom be accepted as substantially correct. The atom is truly a system, composed of a nucleus and planetary electrons. From hydrogen to uranium, the atoms follow a common

plan, based on the equilibration of an electrically neutral system of parts which are interrelated, interdependent, and interacting in such a manner that they form a totality of a higher order. The atoms of one element and those of different elements combine into molecules of a definite structure, so that here again the concept of a 'system' is verified. There is nothing chaotic or haphazard about the molecular arrangement; it is systematic from beginning to end, as the science of chemistry testifies. This can be observed especially in the geometric formation of the *crystals*, and practically all matter tends to arrange itself in crystalline forms, if conditions are right. Analysis of meteorites shows that the systematic structure of atoms and molecules in extraterrestrial objects is the same as here on earth, and we are, therefore, justified in concluding to the identity of structure in the atomic and molecular aggregates of the planets and stars. But this demonstrates a *structural unity* in the universe which argues strongly for the whole world as a 'system.'

Similar to the atom and molecule, the *earth* as a whole is a structural unit, though not so closely knit in the arrangement of its various parts. The interplay of physical forces operates on a much larger scale. Many of these forces conflict with one another, so that chance results are common on earth.

Irruptions from the central core of the earth, the action of winds and waves, storms and quakes, sedimentation and land upheavals — all contribute their share to the development of the earth. The total result, however, tends toward a general structural unification, as can be seen in

the geological and geophysical formations of our globe. The very fact that our earth is a *globe* shows that it is a structural unit, at least in a broad sense of the term, because it is the direct result of the gravitational forces operating in every part, so that the mass of each body acts upon every other. That the entire globe is a unit, is further evidenced by the *magnetic polarity* of the earth as a whole; the earth is a huge magnet, its lines of force enveloping everything from pole to pole. The same forces must operate throughout the whole extent of the universe, because the stars, planets, satellites, and asteroids exhibit the same globular shape; and where the same results obtain, we conclude that the same causes are active. Here we observe the *unity of physical forces* in the universe.

The unity of the *solar system* is beyond question. The sun, with its family of planets, moons, planetoids, meteors, and comets, is a magnificent exemplification of system on a cosmic plane, extending over a diameter of many billions of miles. The interaction of these vast bodies, while noticeable, never seriously interferes with the majestic sweep of each member in its own particular orbit, and the whole solar system moves as a unit on its path in the direction of the constellation of Hercules. It is inconceivable that this should be an isolated and only 'system' among the multitude of stars. More likely, it is but a unit among many units, which together form a much larger unit of solar systems.

Due to the imperfection of our means of observation, to the immensity of the distances which separate the various units, and to the secular and eonic movements of the stars and star clusters, we are unable to piece together the

integral parts of the *whole universe as a system*. However, the fact that enormous star clusters exist and that the giant nebulae show a definite arrangement of material, is proof enough that an interrelation, interdependence, and interaction are present. After all, the same cosmic forces are active everywhere: light, heat, electricity, and gravitation. *Gravitation* binds the whole world together and brings about the balance which gives to each star and system of stars its place and movement in the scheme of the universe as a *totality of integral parts*. Most astronomers do not hesitate to affirm that the Great Galaxy of the Milky Way is a cosmic unit. Late investigations lend support to the view that the Milky Way rotates as a unit around a point situated in the direction of Sagittarius, having a rotation period of, perhaps, something like 250,000,000 years. Whether the great star clusters flanking the Milky Way are relatively independent units or not, is a mooted question. The fact, however, that all galaxies are spanned and enmeshed by the same fundamental force of gravitation, is a strong indication that the entire universe forms *one system*. Everything — bodies and forces — thus conspires to make the world a cosmos.

This description, though necessarily sketchy in outline, should suffice to show that the world is indeed a *system* of interrelated, interdependent, and interacting parts.

MONISM

Closely connected with the subject of cosmic unity is the philosophical doctrine of monism. *Monism* is the doctrine

which maintains a *single, absolute, self-existent principle of being, the sole constituent of all reality*. This implies an ultimate and universal identity of all being. This general tenet has received a variety of shadings in the course of the centuries.

Monism was quite prevalent among the *ancient philosophers*. The *eleatics* professed a monistic philosophy. By confusing the abstract, logical unity of 'being' with the concrete, real unity of 'being,' they ignored the multiplicity of things and came to the conclusion that, since everything is a 'being' and since 'being' is a unitary and unifying idea, all being is one. All change and multiplicity in the world, therefore, is but an illusion. They maintained, however, that this One-Being is a living reality; hence, their system is a hylozoistic or pan-psychic monism. The *stoics* taught that the material alone is real, so that even the soul and God are material. Matter is a condensation or emanation from the original 'something' (τί) or primal world principle. The evolution of all things from this principle takes place with inevitable necessity; eventually, the world principle will destroy all things and begin anew, the process of evolution and destruction being repeated in endless cycles. This is a form of materialistic, deterministic monism. The *neo-platonists* and *gnostics* gave a mystical turn to monism. The world and its contents emanate from God in such a fashion, that in the course of the consecutive emanations things become more and more deteriorated, finally ending in matter which is the worst of all emanations. The entire process is as follows: the One gives rise to intellect; intellect gives rise to the world soul; the world soul gives rise to

plastic forces; and the plastic forces give rise to matter. Matter is unreal, not-being, limitation, evil. Inasmuch as something of God is in all things and all things are something of God, this doctrine is a form of pantheistic monism. Neo-platonism found an echo in a few of the early philosophers of the Middle Ages. Thus, *John Scotus Erigena* (born about 800 B.C.) maintained that God is the essence of all things. A similar doctrine was held by *Amairic of Chartres*. On the other hand, *David of Dinant* identified God with universal matter. Amalric and David lived in the twelfth century. *Giordano Bruno* (1548—1600) also identified God with the world in his system of pantheism.

Monism received its greatest impetus in *modern times*. *René Descartes* (1596—1650) was, to a great extent, responsible for this. Although he himself was in no way a monist, his philosophy became the direct occasion of much of the materialistic and pantheistic philosophy which followed. Descartes was unfortunate in a few of his doctrines, one of which was his view on the essence of mind and matter. For him, “extension in length, breadth, and depth, constitutes the nature of corporeal substance, and thought the nature of thinking substance.”¹ Since the essence of matter is ‘extension’ and the essence of mind is ‘thought,’ body and soul do not form an organism, but are two completely disparate entities, so that the body of man is nothing more than a machine and the spirit or mind of man is not in any sense the vitalizing principle of the body. This gives an ultra-spiritualistic interpretation to the mind and an ultra-mechanistic interpretation to the body. There exists no cognitional communication between mind and body, and

as a result of this ultra-dualism he made it impossible, according to the principle of this doctrine, for the mind to know anything about the body or the external world; whatever ideas or representations the mind has of these realities, it produces entirely in itself and by itself: ideas are thus potentially innate and not derived through abstraction from percepts. Depending on their philosophic temper, many subsequent thinkers advocated either a *materialistic or pantheistic philosophy*, following either the mechanistic or idealistic trend of Descartes' teaching.

Baruch Spinoza (1632—1677) attempted to remove the irreconcilable opposition between mind and matter, as proposed by Descartes, by bringing them into a higher unity. This he did by an arbitrary definition of 'substance' as something which exists in itself and is conceived by itself, so that it does not need the concept of another in order to be understood. Now, there can be only *one such substance*, as expressed in this definition, and that is the infinite substance, *God*. This infinite substance has as its *attributes* 'extension' and 'thought.' Considered under the determination of 'extension,' God is nature or matter; considered under that of 'thought,' God is the human mind. God and all beings are thus one in substance, and this is, of course, pantheistic monism.

Johann Fichte (1762—1814) contended that thought cannot be deduced from being, but being must be deduced from thought; thought, therefore, is the ultimate and only reality. And since all thought is contained in consciousness, there is no reality but the *Ego*. This Ego is the universal consciousness of the Absolute or God. This is pan-egoism.

Friedrich Schelling (1775—1854) also identified the real and the ideal in the Absolute, but he derived both (real and ideal, subject and object, spirit and nature, mind and thing-in-itself) from the indeterminateness of the Absolute. The Absolute gives rise to the real and ideal in its development, so that they are but two phases of the ultimate reality which is the Absolute. *Georg Hegel* (1770—1831) considered the Absolute to be pure *Thought or Idea*, dynamic with immanent activity, not static like Schelling's 'indeterminateness.' Since the Absolute is pure Idea, it evolves by means of a purely logical and rational process of thought into the ideal and the real, into subject and object, into spirit and nature, into mind and matter. The Absolute is continually in a dialectic evolution, so that all being is thought realized. Since all reality is idea, the laws which govern the development of idea are also the laws which govern the development of reality. Nature and spirit do not proceed from the Absolute, as Schelling stated, but the Absolute gradually *becomes* nature and spirit in a process of self-actualization. As the final result of this self-actualization of Being-Idea, all beings and all selves are but modes and manifestations of the Absolute. There is, of course, no creation. All finite beings are but the 'expression,' the 'appearance' of the Absolute; the Absolute becomes all things in a process of logical necessity. These three systems are forms of idealistic, pantheistic monism.

A. *Schopenhauer* (1788—1860) and *E. von Hartmann* (1842—1906) conceived the Absolute in a far different manner from the Absolute of Fichte, Schelling, and Hegel. Schopenhauer was a voluntarist. Instead of the Idea being

the ultimate root of all reality, it is the *Will*. It is as much the Absolute as Fichte's Ego and Hegel's Being-Idea. The universe is but an objectification of the Will, and the essence of the world consists in a blind impulse, an unconscious, irrational striving of the Absolute Will in an eternal struggle for existence. Von Harrmann attempted a reconciliation of Hegel's idealism and Schopenhauer's voluntarism. The Absolute is the Will, but it is guided by ideas; since, however, it is not aware of this, it is unconscious. The Absolute, therefore, is the Unconscious. *Neo-hegelians* subscribe to the general principles of Hegel; but they differ in their methods of approach and in minor points of doctrine. It is characteristic of these philosophers that they approach their problem through experience rather than by means of aprioristic speculations. Prominent among the neo-hegelians are *F. H. Brailley* and *T. H. Green*. For a time idealistic monism had many followers.

Idealism was too extreme to go unchallenged. The pendulum of thought was bound to swing in the opposite direction, especially under the influence of the natural sciences. The fact-finding tendency of the natural sciences forced the scientists to view the world as composed of many individual entities. This tendency, however, induced many scientists and philosophers to embrace the equally extreme doctrine of a *materialistic, mechanistic monism*. While the ultra-spiritualistic trend of Descartes' philosophy reached its highest peak in idealistic monism, the ultra-mechanistic side of his teaching sank to its lowest level in the materialism of recent years. Strictly speaking, materialism is not a monism at all, because it admits that the unity of the

world is the resultant of a multiplicity of beings. However, since it considers matter to be the only reality in existence and derives all beings from matter, it is usually designated as materialistic monism. The main protagonists of this monism of matter were *Karl Vogt* (1817—1895), *Jakob Moleschott* (1822—1893), *Ludwig Büchner* (1824—1899), and especially *Ernst Haeckel* (1843—1919). Haeckel posed as its great prophet. Nothing exists but matter and mechanical motion; and all phenomena, including the mind and its activities, are the result of physicochemical processes. Matter is without beginning and without end, uncaused and indestructible, eternal and absolute. Haeckel often speaks of the 'souls' of atoms, molecules, etc.; but such 'souls' are nothing but mechanical forces of motion. He admits no essential distinction between the organic and inorganic; all is simply matter in different states and conditions of motion.

In attempting to solve the problem of knowledge, many philosophers of our day have advanced views which are nothing but variants of materialism. They either reduce the object known to the knowing subject or the knowing subject to the object known. Some *neo-realists*, for example *Montague*, claim that "all matter is instinct with something of the cognitive function,"² and this is *hylo-psychism*. Hence, the physical and psychical, mind and matter, are ultimately the same reality. And since they always insist that the material objects are real, it follows that mind is reduced to matter. A similar doctrine is held by the critical realists. They are *pan-psychists*. The universal principle, from which all things spring is 'mind- stuff,' so that the whole world is

really, in a sense, alive, only it is unaware that it is living. *Emergent evolution* is a doctrine of evolutionary naturalism, which maintains that nature is the product of evolution in such a manner that entirely new and unpredictable properties originate through synthesis and thereby form new and higher levels of reality. Such properties 'emerge' with specific characters not discoverable in the former (lower) levels. *Lloyd Morgan*, L. T. Hobhouse, C. A. Strong, D. Drake, E. Noble, R. Sellars, and others, are defenders of the theory of 'emergence.' For *S. Alexander* the ultimate evolutionary principle of the world is *Space-Time*. It has in the beginning no quality except the spatio-temporal quality of motion, but subsequently everything 'emerges' from it into the world we know. None of these theories consider the world as having had a beginning; God as the creator is left out of the picture entirely. According to all indications, these doctrines are species of materialistic monism, some mechanistic, some hylozoistic. In every case they seek the derivation of all beings in the world from some root principle of matter.³

If we now analyze these various theories, we find that monism falls into two broad classes. Monism in the *strict sense* defends the *entitative unity* of all being. Such a system is opposed to a multiplicity of things as separate entities. There exists nothing but a numerically single substance or being, and this is God or the Absolute. Monism in a *wider sense* seeks to reduce the multiplicity of beings to the *essential unity* of a *single kind* of entity. They admit that things are not numerically one, but many; however, they deny the essential differences between things and

assert that they evolve from one root principle which constitutes them all as the same kind of substance or being. To this monism in a wider sense belong the pantheistic systems of the stoics, neo-platonists, and gnostics; pan-psychism, hylozoism, and hylo-psychism; mind-stuff and space-time theories; plain materialism; and most of the philosophy of emergent evolution.

From another point of view monism may be said to be either *pantheistic* or *naturalistic*. *Pantheistic* monism starts with *God* or the *Absolute* as the One-Being and derives the present world from this One-Being through emanation or immanence or determination. According to the doctrine of 'emanation,' the One-Being (God or the Absolute) develops the world out of its own substance, so that a portion of the One-Being is present in each individual being. The doctrine of 'immanence' appears in two forms. According to the one form, the One-Being develops into all things in such a manner that they are real affections or modifications of the One-Being's substance. According to the other form, the world is a mere manifestation of the One-Being. In both forms, the One-Being is 'immanent' in all things in such a fashion that they are really not distinct from the One-Being itself. According to the doctrine of 'determination,' the One-Being begins as the most indeterminate sort of being and then develops into the determinate beings of the world, becomes more and more determinate in its own being through this evolutionary process, working out its own perfection unto completion through these successive stages of self-determination and self-realization. *Naturalistic monism* starts with the *world* itself, without any reference

to God or the Absolute. This type of monism also appears in a variety of forms. The principle of a natural *evolution* is accepted by all. The primordial stuff, out of which the present world evolved, is either lifeless matter, and in this theory life and mind are looked upon as physicochemical phenomena of matter; or it is animated matter, so that everything without exception is living; or it is a neutral stuff, which evolved into mind and physical bodies. Some theorists even go so far as to state that this evolutionary process will eventually develop Deity as its final result. Although naturalistic monism admits that the world, as presently constituted, consists of a multiplicity of beings, the adherents of this system claim that their theory is a true 'monism,' because it derives all beings in the world from a single indeterminate kind of primordial stuff. In this it differs radically from pantheistic monism, which defends the substantial, entitative oneness of all things with God or the Absolute, the One-Being.

It should be obvious from this, that the unity of the world as a cosmos receives a unique and comprehensive interpretation in these systems. What are we to think of these views?

CRITIQUE OF PANTHEISTIC MONISM

Pantheistic monism identifies, in one way or another, the world with God or the Absolute. There exists but a single substance, the One-Being (God or the Absolute), and the universe is either an emanation, a modification or manifestation, or a determination of the One-Being. The

One-Being and the universe are, therefore, entitatively one and the same substantial reality. That, the pantheists say, is the ultimate reason and ground for the unity in the world.

We reject *pantheistic monism* as being contrary to *experience* and *reason*.

It is contrary to *experience*.

Unless we wish to indulge in fantastic speculations which have no foundation in fact, we must base our cosmological and philosophical theory of the universe on the experiential data of *scientific observation*. Scientific observation and verification must form the basis and the touchstone of any theory which lays claim to being a true explanation of the universe. The reason is simple: our knowledge of the universe is acquired through observation, and observation is a form of experience. All experience, in its final analysis, rests on the testimony of our *consciousness*. The truth value of our consciousness cannot be denied or seriously doubted, without destroying the foundation of the structure of our knowledge and plunging the mind into complete skepticism.⁴ Now, consciousness in no way bears out the contention of pantheistic monists, that all things are entitatively one with God or the Absolute; on the contrary, it is an irrefragable witness to the entitative multiplicity of beings in the universe. A brief survey of the facts will establish this truth beyond reasonable doubt.

Three main factors enter into this problem: the human *mind*, the human *body*, and the external *world*. The body, as our consciousness testifies, is an extra-mental reality, distinct from the mind; but it belongs to the human Ego as an integral part, together with the mind, and as such is

extra-mental but intra-Ego. The physical world, on the other hand, is extra-mental, because outside the thinking human mind, and also completely external to the perceiving subject or person; as such, it is both extra-Ego and non-Ego. Our consciousness is witness to the fact that these three types of reality are entitatively distinct, the one being different in entity from the other and therefore not identical.

We come to the same conclusion, when we consider the fact of *other minds*. No sane person can doubt the existence of other minds' which are entitatively distinct from our own. Our experience is witness to the fact that we have direct and immediate knowledge of no other mind but our own. And yet we are certain that other minds really exist. This is proved by *language*, because we communicate with these minds through the medium of words which signify ideas. That these other minds are existent realities distinct from myself is clear, because the *ideas* which I receive in the course of this thought-communication from the other minds are often new to me and are evidently given 'from without.' That these ideas are not the product of my own thinking, is an incontrovertible certainty: they are frequently foreign and antagonistic, even contradictory, and in many instances I experience great difficulty in understanding them. Many times it happens that these 'other minds' attempt to communicate ideas to me in a language which I do not understand. How could this be so, if these minds were entitatively identical with my own? There can be no doubt, then, that they have an existence independent of myself and are entirely distinct beings. But that proves that the beings of the universe are not a substantially identical One-Being,

otherwise it is incomprehensible why this One-Being should not be able to understand its own language and grasp its own ideas.

Needless to say, the *natural sciences* are in accord with our view, not with that of pantheistic monism. Astronomy, physics, geology, anthropology, zoology, botany, chemistry — all lead to the inevitable conclusion that nature is a real world of existing, discrete, entitatively distinct bodies, some living and some nonliving. The ultimate particles of matter, electrons and protons, are irreducible entities. The sciences find nothing to indicate that all things are identical in the One-Being.

And thus we see that pantheistic monism, with its doctrine of a single substantial entity, is contrary to experience.

Pantheistic monism is *contrary to reason*.

It is based on a *confusion of concepts*. All the differences between things, pantheists say, are neutralized in the concept of *being*. Each individual thing is a 'being,' whether it be spiritual or material, whether it be an element or a compound, whether it be organic or inorganic, whether it be an atom or a star, whether it be the world or God or the Absolute. The concept of 'being' is realized in each and in all together; and it is a unitary concept, meaning simply 'that which exists.' Since the concept of 'being' is one, all that exists is one being; hence, all things are identified in the One-Being, God or the Absolute. Pantheists fail to see that this line of thought rests on a *confusion of the real and logical orders*. The unity of 'being,' predicated of all things here, is an abstraction of the mind, a logical unity, made by

ignoring the real differences which exist concretely in the things. I can, of course, compare living and nonliving beings, ignore the real difference between 'life' and 'lifelessness,' and focus my attention solely on the fact that they agree in the concept of 'being.' I can also compare material and spiritual things, God and the world, and concentrate solely on their 'being.' Thereby I arrive at the one concept of 'being' which is common to all things. It is, however, only in my *concept* that they are viewed as 'one'; in their *reality* they are still *many* and *different*, because I cannot remove their multiplicity and their differences in the 'real' order by merely ignoring them in the 'conceptual' or 'logical' order. Our experience, as was pointed out, proves that things are multiple and entitatively distinct in the real order of things, and the logical unity of all things in the concept of 'being' by means of mental abstraction does not make all things actually 'one' in the real order: they remain multiple and distinct beings, no matter how we conceive them in our ideas. Pantheistic monism, since it is based on a confusion of the real and logical order, is thus seen to rest on an illogical foundation.

Furthermore, pantheistic monism destroys the most fundamental *laws of thought and being*. The universe, as it exists, is composed of beings having activities and properties which are *contrary* and *contradictory* if present in one single reality. Some beings are inorganic, others organic; some are sentient, others non-sentient; some are rational, others irrational; some perform acts which are morally good, others perform acts which are morally evil; some assist one another, others combat and destroy one

another. But these are contrary and contradictory activities and properties. If, then, there exists but a single substance, a solitary One-Being, it would be simultaneously living and nonliving, sentient and non-sentient, rational and irrational, morally good and morally evil, self-developing and self-destroying, etc. In that case, however, the *Principle of Contradiction* is abolished and *Contradiction* becomes the supreme law of thought and being; this we cannot admit.

Similarly, if pantheistic monism were true, we must abandon the *Principle of Sufficient Reason*. The universe is supposed to be an emanation, evolution, or determination of the One-Being (God or the Absolute). Now, the *reality of the result* of this process of world formation was either present in the One-Being before the process began, or it acquired this reality by means of this process. But if the One-Being possessed all this reality beforehand, why should the process of emanation, evolution, or determination occur at all? What could the One-Being gain by it? But if the One-Being lacked all this reality in its original condition, whence could it receive it? Not from itself, because it did not have it in the first place. Not from another being, because no other being exists which could give it. In the first case, we have no sufficient reason to explain why there should be an emanation, evolution, or determination of the One-Being in the formation of the universe; in the second case, we have no sufficient reason to explain whence the new reality in the universe could be acquired. We have but two alternatives: either pantheistic monism must be rejected as an irrational system, or the Principle of Sufficient Reason must be thrown into the discard. The latter alternative involves the

abandonment of reason and the bankruptcy of all knowledge, in which case, pantheistic monism itself as a system of thought is also of no value. The only thing left, then, is the rejection of pantheistic monism.

Finally, the very *concept* of the 'One-Being,' of 'God,' of the 'Absolute,' as envisioned by the pantheists, is *illogical*, because contrary to reason. The existence and nature of God, as the Supreme or Absolute Being, is proved and explained in theodicy, a separate department of philosophy. Here we assume the findings of theodicy without question or proof, and we argue as follows. A being which is *uncaused* and which, therefore, has the ground of its existence and essence in itself (*a se*), must be infinitely perfect, unchangeable, absolutely independent, without composition of any kind, supremely intelligent, and personal. The pantheistic One-Being, God or Absolute, has none of these attributes, no matter what type of pantheism we examine. Since the One-Being is identical in substance with the universe, the attributes of the universe must be the attributes of the One-Being. But the universe, as was shown repeatedly, contains beings of various degrees of perfection in their entity, is in a continuous process of change, is dependent on the mutual interaction of its parts, is a totality composed of many discrete members, is as a whole without inherent intelligence, and is devoid of personality. The pantheistic God or Absolute or One-Being is thus seen to be a mass of contradictions in its very concept.

Pantheistic monism, therefore, is in opposition to the facts of experience and to the principles of reason. Its

attempt to explain the unity of the world by means of a pantheistic interpretation, ends in failure.

CRITIQUE OF NATURALISTIC MONISM

Naturalistic monism, while it admits the multiplicity of beings in the universe, derives all beings from a single indeterminate kind of primordial stuff. All types of beings and the universe as a whole originate from it by means of a process of *natural evolution* through no other agency than the *inherent power* of this stuff itself. If these philosophers would accept an omnipotent, all-intelligent, extramundane Supreme Being who created primordial matter and endowed it with evolutionary *tendencies*, much of this doctrine could be maintained without serious objection. This, however, is not the case. Naturalistic monism attempts to explain the origin and development of the world in all its beings, inorganic and organic, on purely *naturalistic* principles. Either explicitly or implicitly they deny the existence of God and spirit, and seek to eliminate the essential distinction between living and nonliving beings. Hence, it is the avowed purpose of these monists to explain everything in the universe through evolution, without interference or direction by any extramundane agency; and in order to account for the existence of organic beings, they either reduce vital function to a phenomenon of inorganic matter, or they postulate that all matter was and is always instinct with life, or they assume that life evolved through the powers of nature from inorganic matter. Naturalistic

monism is thus in diametrical opposition to the *dualism* of God and the world, of life and non-life, of spirit and matter.

We reject *naturalistic monism* as an *inadequate explanation* of the world and its unity. Naturalistic monism has no foundation in science.

Unlike the pantheistic monists, naturalistic monists make a great showing of scientific knowledge and appeal constantly to scientific facts. Modern science boasts of its 'exactness in observation and experiment and accepts no conclusion unless based on data which can be verified by scientific methods. When, therefore, some of the monistic philosophers assert that all matter is *instinct with life*, so that all beings in the universe are living beings, one should expect this assertion to be borne out by definite scientific data; only then can such a far-reaching conclusion be warranted. Science, however, does not support this contention. On the contrary, it is the unanimous verdict of the natural sciences that the immense bulk of the universe is *inorganic* and *nonliving* and that only a relatively insignificant portion possesses life. Even on our earth the number of plants, animals, and men, when compared to the earth as a whole, is very small. The characteristics of organisms are so marked and clear that scientists find practically no difficulty in distinguishing them from inorganic elements and compounds. It is true, of course, that scientists are often compelled to revise their conclusions and alter their hypotheses; this usually happens when the data are very meager and obscure or when the method of experiment is unusually difficult and complicated. In the case of organisms, however, there is

such a wealth of material and the research into this material has gone on so long and so thoroughly, that all reasonable doubt is excluded. While there might be some question in individual instances as to the exact classification of a certain being, there is no question about the general classification of 'living' and 'nonliving,' of 'organic' or 'inorganic' bodies. That type of naturalistic monism, which seeks to eliminate the distinction between living and nonliving beings by the claim that everything in the universe is alive, leaves the realm of science and disports itself in the realm of fancy.

Those monists who defend the evolution of an original *neutral* stuff into *inorganic* and *organic* beings through 'emergence' or any other method, also run counter to the facts established by the exact sciences. Such an evolutionary process would be a plain case of *spontaneous generation*, namely, the origin of a living being out of nonliving matter through natural causes. Scientific investigation of the most rigorous sort, following the experiments of *Louis Pasteur*, has given the unshakable verdict that spontaneous generation never occurs: every living being derives its origin from another living being, every cell from another cell, every chromosome from another chromosome. This being so, it is evident that naturalistic monism is entirely unscientific, when it postulates the evolution of organisms from some neutral stuff. Nor can its proponents save their theory by assuming that *organisms existed from the beginning*. For one thing, such an assumption is contradicted by geology and paleontology, which find no evidence of life on our globe in

its earlier geologic history. Again, such an assumption would give the deathblow to the theory of naturalistic monism, inasmuch as the primordial matter would not be monistic, but *dualistic*, since the beings of the universe would be derived from two distinct and mutually irreducible principles, living and nonliving matter.

From whichever standpoint we view naturalistic monism, it is seen to have no foundation in natural science. Science contradicts its postulates.

Naturalistic monism has *no foundation in philosophy*.

Sound philosophy must maintain the *essential distinction* between living and nonliving matter, between organic and inorganic beings. We know the essence of a thing from its properties and activities, because we are incapable of perceiving the essence directly. When, therefore, things differ in their properties and activities *radically and fundamentally*, they must be adjudged to differ in their essence or substantial constitution, for the essence is the root principle from which the properties and activities emanate and is the ultimate reason for all that a thing is and does. Now, the properties and activities of organic and inorganic beings differ radically and fundamentally. Consequently, there is an essential difference between them.

The organism, which is lowest in the scale of life and closest to the inorganic world, is the *plant*. The plant has *vegetative function* only. This function manifests itself in nutrition, growth, and reproduction. These processes occur primarily in the cells of the vegetative being: the cells assimilate the nutritive material, multiply and thus produce

growth, and finally develop special germinal cells which give rise to new individuals of the same species. The basic function is *assimilation*, whereby the organism takes in foreign material and converts it into its own living substance.

The distinguishing feature of vegetant beings, setting them completely apart from inorganic nature, consists in this *assimilation*. We find nothing similar to it in inorganic beings. *Chemical change* is the only activity of inorganic beings which might compare with assimilation. There is, however, a vast difference between the two. In chemical change a new chemical substance arises, different from the component substances in properties and activities; water, for example, differs from oxygen and hydrogen in its behavior to such a degree that one cannot recognize the two in the compound. In assimilation the change is even more profound, but of an entirely different character; the organism assimilates the nutritive material in such a manner that the material becomes an integral part of the organic substance, while the organism itself retains its complete identity and does not change. In chemical change, therefore, the component substances lose their individuality; in assimilation, on the other hand, the vegetant being retains its individuality intact, changing the nonliving material into living substance.

Among all the known inorganic substances, the *crystal* bears the greatest resemblances to the lowest forms of plant life. A comparison between the crystal and the plant should, therefore, prove fruitful in establishing the difference between living and nonliving matter. The activity

of the crystal consists primarily in this, that the atoms which enter into its composition are arranged in such a manner of disposition that the entire crystal is built up in geometrical symmetry. Here again, however, we observe a vast difference between *crystallization* and *assimilation*. In the crystal the entire structure consists of homogeneous atoms and molecules, so that the crystal itself is nothing more than the aggregate of a number of chemically identical atoms and molecules, In the organism the various parts are structurally different and consist of chemically heterogeneous atoms and compounds, subservient to the needs and purposes of the organism as a complete individual in itself. Again, the structure of the crystal is formed by the symmetrical juxtaposition of the atoms and molecules, and these atoms and molecules undergo no change in this process. In the organism, however, the atoms and molecules after assimilation undergo a radical change, so that combinations are made which they in their natural inorganic state are incapable of making. Furthermore, the atoms and molecules in the crystal perform no new activities and acquire no new properties different from those which they already possess. In the organism these same atoms and molecules become living substance and perform activities which, because vital, are of a higher and entirely new order. Finally, the crystal is stable in its structure and, once formed, reveals no activity of self-development, self-perfection, and reproduction. In the organism, however, each cell functions as a unit, and groups of cells form special organs which function as a unit, and all cells and special organs combine to form the

organism which functions through them all as a unit. Each cell and organ nourishes and repairs itself, grows to maturity, and functions as an integral part of the organism as a whole; the organism itself possesses individuality, is endowed with the power of self-preservation against harmful outside agencies, develops to full maturity, ages, and then, after preserving the species by evolving reproductive cells, dies. Such differences are not superficial; they are radical and fundamental.

If life were nothing more than a certain combination of physical and chemical energies, the activities of living beings would of necessity obey the laws prevalent in physical and chemical nature. But life has laws of its own, different from those of the inorganic world. Therefore, life must issue from an essence or principle which is totally different from that of inorganic beings. The activities of vegetancy, sentiency, and rationality are without question of a higher order than the activities of physical and chemical energies. And since no effect can be greater than its cause, and since no cause can produce an effect of an order higher than its own inherent capabilities, the conclusion is inescapable that *life could not have originated from nonliving matter*.

As a philosophic interpretation of the unity of the world, therefore, naturalistic monism is seen to be an inadequate explanation of the facts; it is scientifically and philosophically unsound and must be rejected. Organic and inorganic beings are irreducible ultimates in the universe. *Dualism*, not monism, is the signature written over all.

Unity exists in the cosmos; of that there is abundant evidence. Neither pantheistic monism nor naturalistic monism can give an adequate account of how this unity is affected. In a later chapter we will see that the only adequate explanation lies in acknowledging an extramundane Creator and Designer.

SUMMARY OF CHAPTER XVI

Is the world a cosmos?

1. *Unity of the Universe.* By 'cosmos' we understand an assemblage of diverse units so combined as to constitute an integral whole and to function in unison in obedience to some form of control; in other words, to be a 'cosmos' the universe must be an 'orderly system.'

The universe consists of the same uniform elements, which in turn consist of the same kinds of subatomic particles. There is, therefore, a *constitutional unity*. Each single atom, molecule, and crystal possesses definite structure. There is, therefore, a *structural unity* throughout the universe in its ultimate parts. The *earth*, as a whole, is a unit; this is evidenced in its globular shape, structural formation, and magnetic polarity. The same forces operating on the earth operate throughout the world. Here we have the *unity of physical forces*. The solar system manifests unity. In the universe as a whole we find the same cosmic forces active everywhere: light, heat, electricity, and gravitation. Everything points to the fact that the universe is a *totality of integral* parts, a system of interrelated, interdependent, and interacting parts.

2. *Monism.* Monism is the doctrine which maintains a single, absolute, self-existent principle of being, the sole constituent of all reality. This implies an ultimate and universal identity of all being.

Monism appears in many forms and in many systems of thought. They can be reduced to *two broad classes*. Monism

in the strict sense defends the *entitative unity* of all being; there exists but a numerically single substance or being, God or the Absolute, the One-Being. Monism in a wider sense seeks to reduce the multiplicity of beings to the *essential unity* of a *single kind* of entity. Or, we may reduce all these types of monism to pantheistic and naturalistic monism. 'Pantheistic' monism starts with God or the Absolute as the One-Being and derives the present world from this One-Being through emanation or immanence or determination. 'Naturalistic' monism starts with the world itself; the world originated through natural evolution from some primordial stuff without outside direction. This primordial stuff is either lifeless matter, or animated matter, or neutral stuff evolving into mind and physical bodies.

3. *Critique of Pantheistic Monism.* It is *contrary to experience*. Our consciousness testifies that we consist of mind and body, and the two are entitatively distinct, not identical in being. Consciousness also testifies to the existence of *other minds* and *other bodies* as real as our own, but entitatively distinct and different. To avoid skepticism, we must admit that the universe consists of a multiplicity of beings.

Pantheistic monism is also *contrary to reason*. It rests on the confusion of the ideal and real orders; all things form a 'logical' unity in the concept of 'being,' but in their actual existence they are many and different. It destroys the most fundamental *laws of thought and being*. Contradictory attributes would apply to the same reality, and thus the Principle of Contradiction would no longer hold. There would be no sufficient reason for the evolution of the One-

Being, if it possessed all reality before it began evolution; and if it did not possess all reality from the beginning, there would be no sufficient reason for the new reality acquired. This is contrary to the Principle of Sufficient Reason. Finally, the very *concept* of the pantheistic One-Being is illogical. The uncaused Being must be infinitely perfect, unchangeable, absolutely independent, without composition, supremely intelligent, and personal. The pantheistic God or Absolute or One-Being has none of these attributes.

4. *Critique of Naturalistic Monism.* It has *no foundation in science*.

In seeking to eliminate the essential difference between living and nonliving beings, some monists assert that all matter is *instinct with life*, so that all beings in the universe are really living. This is contrary to the unvarying verdict of science. Others maintain that the original stuff was *neutral* and eventually evolved into inorganic and organic beings. This would be a case of *spontaneous generation*. This, too, is contrary to the verdict of science.

Naturalistic monism has no foundation in philosophy. Sound philosophy must maintain the essential distinction between organic and inorganic beings, because their properties and activities *differ radically and fundamentally*. Assimilation, the characteristic feature of vegetative life, differs altogether from chemical and physical activities; a comparison between assimilation in a *plant* and the activity of chemical change or crystallization shows this clearly. Life has laws of its own, different from those of the inorganic world. Since vital function is superior to inorganic function,

life could not have originated from nonliving matter because no cause can produce an effect of an order higher than its own inherent capabilities.

Hence, as a philosophic interpretation of the unity in the world, neither pantheistic nor naturalistic monism is satisfactory. *Dualism*, not monism, is manifested in nature.

Chapter 17

CAUSALITY AND LAW

COMMON EXPERIENCE AND SCIENTIFIC RESEARCH AGREE that the cosmos is an immense theater of action and change.

Action and change necessarily involve the concept of *causality*. By 'causality' we understand *the positive influence of one thing in the production of another*. The producing agent is the 'cause'; the produced reality is the 'effect'; the positive influence in the production of the effect on the part of the agent is 'causality.' Hence, the production of an effect involves a 'change,' and this change is brought about through 'action' of the cause.

There are *four main types of causes* which contribute in a positive manner toward the production of things. There is that 'out of which' a thing is made, and this is the *material cause* (matter). There is that 'by which' it is made, and this is the *efficient cause*. There is that 'through which' it is made, thereby becoming specifically what it is, and this is the *formal cause* (form). And then there is that 'on account of which' or 'for the sake of which' it is made, and this is the *final cause* (end, purpose).¹ That matter and form actually contribute toward the essential production of things as

their material and formal cause, has been previously shown (Chaps. 12, 13); they are constitutional factors which bring about the genesis of the composite body whenever such a body comes into being. The existence of causality, in the sense of the operation of *efficient* and *final* causes in the universe, must now be examined and proved.

CONCEPT OF EFFICIENT CAUSE

Scientists often speak of *physical causes*, and the unwary might receive the impression that they mean what the philosophers term 'efficient causes.' The two terms, however, need not coincide in meaning. Thus, John Stuart Mill says: "The causes with which I concern myself are not *efficient*, but *physical* causes. They are causes in that sense alone, in which one physical fact is said to be the cause of another. Of the efficient causes of phenomena, or whether such causes exist at all, I am not called upon to give an opinion."² What are here termed 'physical causes' are nothing more than the necessitating and indispensable *conditions or antecedents* of physical events. Mill thus sharply differentiates between 'physical causes' and 'efficient causes,' the latter being the 'producing agencies' which exert a positive influence in the actual production of a thing. The ordinary scientists, in the work of their experiments and in the observation of nature, do not make such a distinction, but consider 'physical causes' to be identical in meaning with 'efficient causes.' The philosophical scientist, however, may make such a distinction, and this distinction should be noted.

In order to have a clear concept of efficient causality, we must distinguish it from a *condition* or an *occasion*. A 'condition' is something required in order that an efficient cause can act, but it does not contribute any positive influence toward the production of the effect itself. Thus, clear weather or 'visibility' is a condition for the effective and safe flying of an airplane; a fog, extending over a large part of the area over which the aviator must fly, would be an adverse condition making his flight hazardous. Obviously, however, neither the clear sky nor the fog have anything to do with the actual flying of the ship. An 'occasion' is a circumstance or combination of circumstances which affords an opportunity for an efficient cause to act. For example, the birthday party of a friend may be the occasion why the pilot desires to fly his ship to a distant city. Here, too, the occasion of the birthday party has nothing to do with the actual flying of the ship. The efficient cause of the actual flying, which is the produced effect, is the pilot himself and the mechanism of the airship; they contribute in a positive manner toward the production of the effect of traveling through the air. 'Conditions' and 'occasions' exert an indirect influence on an *agent to act*, but it is the action of the agent which produces the effect, and it is this *productive action* of the agent which constitutes 'efficient causality.'

In order to obtain a better understanding of the nature of efficient causality, in so far as it affects the problem under discussion, a few of the *main kinds* of efficient causes must be enumerated.

First Cause and Second Cause. By 'First Cause' we mean one which is absolutely independent of any other cause or being, and on which the causality of every other cause depends. By 'second cause' we mean one whose causality is dependent on some other cause or being. In the sense defined, God alone is the 'First Cause'; all creatural causes are 'second causes,' because their whole being, and therefore also their efficient causality, is derived from, and dependent on, Him as their Creator.

Physical and Moral Cause. A 'physical' cause is one which produces an effect by its own direct action. Thus, the electric spark in the motor of an engine ignites the volatilized gasoline; a boy throws a stone and breaks a window; a soldier shoots an enemy sniper and kills him. A 'moral' cause is one which inclines a free agent to perform an action. Thus, a candidate for office persuades the people to vote for him; a criminal extorts money through blackmail; a mother threatens her child with punishment, if he does not behave.

Principal and Instrumental Cause. By a 'principal' cause we mean an efficient cause which is the primary agent and produces an effect in virtue of its own power. By an 'instrumental' cause we mean an efficient cause which produces an effect in virtue of the power of another cause. Thus, when a sculptor carves a statue, he is the principal cause, since he wields the hammer and chisel; the hammer and chisel are instrumental causes under his control and direction.

Cause per se and Cause per accidens. A 'cause per se' is one which has the natural tendency to produce a particular

effect or, if it be a free agent, which intends freely to produce it. A cause per accidens' is one which produces an effect toward which it has no natural tendency and which the free will (if that be the cause in question) does not intend. When a loose tile falls from the roof, gravity is the 'cause per se' of its falling; but if, in falling, the tile hits a passerby, gravity is the cause per accidens' of this effect, because it has no natural tendency to drop things on people passing by. When a hunter fires his rifle at a deer, he is the 'cause per se' of the shooting, because he intends the shooting; but if the bullet misses the deer and wounds a man, hidden from view in the distance, he is the 'cause per accidens' of the wounding, because he did not intend this effect.

Proximate and Remote Cause. A 'proximate' cause is a cause which produces its effect by immediate action. A 'remote' cause is a cause which produces its effect through the direct action of some intermediate cause or causes. When a pool player sends the cue ball on its way with a blow from his cue, he is the proximate cause of the speed and direction of the cue ball, the cue itself being used as an instrumental cause; but when the cue ball contacts the other billiard balls and sends them in different directions, the player is only the remote cause of this effect.

Total and Partial Cause. A cause is a 'total' cause, when the entire effect is produced by its action; if only a part of the entire effect can be attributed to a particular cause, it is a 'partial' cause. Thus, when a batter in a baseball game knocks a home run, he is the total cause of this score; but he can be only a partial cause of the winning of the game,

even if the score be 1 – 0, because all the members of the team must contribute their share toward the game as a whole.

Necessary and Free Cause. A ‘necessary’ cause is one which is determined by its nature to produce a certain effect, provided the requisite conditions are present. Thus, when the proper conditions of heat, moisture, soil, etc., are present, a normal seed must begin its vital function; when a stone is thrown into the air, gravity must pull it back to the earth. A ‘free’ cause is one which is not compelled to act, even if all the requisite conditions are present. Thus, man is free in many of his actions, such as eating, smoking, playing, etc.

We are now ready to discuss the question of the existence of ‘efficient causality’ in the universe.

THE EXISTENCE OF EFFICIENT CAUSES

After all that has been said about chemical and physical changes, about the mutual interaction of bodies upon one another throughout the universe, it hardly seems necessary to prove the existence of efficient causality. However, some philosophers have denied, or at least doubted, the possibility of knowing or proving its existence, and their contention cannot pass unnoticed.

The *opposition* to the concept and fact of efficient causes is based on various grounds.

The defenders of *mechanical atomism* admit nothing in the universe but matter and mechanical motion. Bodies are completely inert, passive; they have no spontaneous activity

of any kind. All movement comes from an outside applied force. This assumption of the complete passivity of material beings is, as was pointed out before (Ch. 11), false. It is disproved by the fact of *radioactivity* in certain elements. The disintegration of these elements and the expulsion of alpha and beta particles occur spontaneously and are not brought about by outside agencies; the energies inherent in the core of the atoms produce these powerful effects and radical changes. The active production of a change, however, is the same as 'efficient causality.'

The *occasionalists*, like Malebranche and others, deny all creatural activity and causality. In their view, causality, since it implies the production of some new reality, amounts to *creation*, and creation is an activity reserved to God alone. Hence, when creatures appear to be active and produce effects, it is really God who is active in and through them. At best, then, creatures are 'occasional causes' for the activity of God, inasmuch as they furnish the 'occasion' for God to produce effects in nature. Occasionalists fear that the distinction between Creator and creature would be obliterated, if creatures were capable of self-activity and causality. This fear is ungrounded. For one thing, whatever power of efficient causality creatures may have, they have from the Creator, not from themselves. Then, their activity would not be creation, because creation means to produce the complete substance without any pre-existing material from which it is taken; creatures, through their efficient causality, merely change a pre-existing substance from one kind of being into another kind of being. Finally, the facts are too clear: man, for example, is conscious of producing

effects through his own activity, as when an artist paints a picture, or a farmer plows his field, or a sprinter runs a race. To deny the trustworthiness of our consciousness in such matters, is tantamount to complete self-delusion and would lead to universal skepticism.

Kant and his followers denied the objective validity of our concept of efficient causality because of his peculiar theory of knowledge. According to this theory, we can know nothing but 'phenomena,' and these exist only in the mind; the noumena' or 'things-in-themselves,' as they exist outside the mind in external nature, man can never know. 'Efficient causality' is a *category* of the mind, is purely mind-made, and as such has only subjective value for the mind and its operations; whether anything corresponds to this category in external nature, is beyond the knowledge of man.³ This view is erroneous. It rests on the assumption that we can know nothing of things outside our own mind. In that case, however, we could know nothing of *other minds*, since they would assuredly be 'things-in-themselves.' That we do actually have a knowledge of 'other minds,' is clearly proved by the fact of language. Hence, Kant's main objection against the existence of causality in the universe rests upon a false assumption. In fact, if we can prove the existence of causality in the case of man himself, we prove the existence of causality in the universe, because man is a part of the universe. This will be proved shortly.

Phenomenalists, like Hume, Mill, and many others, also deny the objective validity of the concept of efficient causality. According to these philosophers, all that we can know is what we can perceive with our senses. The senses

merely reveal the *phenomena* of things. Events appear in *invariable sequence*, the one preceding and the other following in time and place. Because we always perceive this 'invariable sequence,' habit and the association of ideas delude us into imagining the relation of 'cause-and-effect' to exist between them, the earlier event being the 'cause' and the later event the 'effect.'

Phenomenalists are sadly mistaken. We do not at all consider invariable sequence to be real causality. Night and day, winter and spring, follow each other in an *invariable sequence of events*, but we do not on that account consider night to be the cause of day or winter to be the cause of spring. Nor is it true that we derive our concept of the cause-and-effect relation from the observation of the *frequency* of an occurrence through *habit* and the *association of ideas*. We apply this relation of cause-and-effect to events which occur only once, so that habit and the association of ideas can play no part in our judgment. Thus, when the first airplane crashed, the question was immediately asked: "What caused it to crash?" No 'invariable sequence' was required for man's mind to realize that something had to produce this disastrous effect. Similarly, when the first steamboat, or the first locomotive, or the first telephone, or the first automobile, went into operation, no one waited for the hundredth or the thousandth appearance of the phenomenon, in order to establish an 'invariable sequence' and then apply the principle of the relation of cause-and-effect. The very first appearance was sufficient to inquire into the cause of the perceived effect: "How does it run? What makes it go? How

does it work? What causes it to perform as it does?" The mind perceives that a new reality has come into being, an effect has been produced, and there must be a cause, even in the *first instance of occurrence*, to account for it. True, the senses perceive only the external phenomena and not the internal power which produces the change, but *reason* demands that such a power exist as the 'efficient cause,' otherwise the 'effect' could not occur.

Having disproved the assumptions on which the opposition to efficient causality in nature is based, we now proceed to the *positive proof* of the existence of efficient causality.

Experience proves efficient causality.

First, there is internal experience. Consciousness is the ultimate source of all true knowledge. We cannot doubt the truth-value of consciousness without doubting the validity of all human knowledge. But consciousness is a million-fold witness to the fact of efficient causality *within our own being*. We have many internal activities, such as imagining, thinking, desiring, willing. We are conscious that they not only take place *in* us, but that they are also produced *by* us through *our own action*; in other words, they are produced in us as effects, and we are the efficient causes. Thus, to give a simple example, we propose a problem to ourselves and desire to solve it. We then seek the solution of the problem through a lengthy process of reasoning, using ideas, judgments, and inferences, which we ourselves elaborate. We are conscious of the fact that we inaugurate and conduct the entire activity involved in this process through our own deliberate action; we *produce* this

complete chain of events within us, and that is 'efficient causality.' And since we are a part of the universe, it follows that efficient causality actually exists in the universe. This proof, taken from our internal experience, really suffices to prove our point. Then, there is *external experience*; it also proves conclusively that efficient causality exists in nature. I take some boards, cut them, nail them together, and form a table. I mix some paints, dip a brush into the mixture, and proceed to decorate the room. I get behind the wheel of my automobile, turn on the ignition, step on the starter, feed the engine, manipulate the gears, release the clutch, and drive the automobile through the streets. I take pen, ink, and paper, and begin to write a letter or an essay. And so with a hundred other operations. No one can convince me that all this shows nothing more to me than a set of phenomena in invariable sequence in which there is no efficient causality present. I know beyond the possibility of doubt that I am the *producing agent* of these various phenomena and that these events owe their existence to the positive influence of my activity; in other words, I am the efficient cause of these effects. The important point to consider here is: these are 'external effects' occurring in 'external nature' and not merely in my mind.

Reason demands efficient causality in nature.

Phenomenalists commit the supreme error of admitting no knowledge except sense knowledge to be valid and true. They overlook the fact that *reason* must interpret the data of sense before we can have true knowledge. All science and philosophy is a 'knowledge by reason,' not a 'knowledge by sense.' The demands of reason must be

satisfied, because that is the essence of science and philosophy. Reason, however, demands that we admit the existence of efficient causality *in other beings* besides ourselves.

If I do a bit of carpentering and produce a table, I am the efficient cause or producer of that table. If, then, I perceive other men carpentering, whether it be in the making of a table or of a chair or of a house or of anything else, what am I to conclude with regard to their actions? They are doing the same thing I did; they are performing the same sort of action. Consequently, reason demands that I conclude that they, too, are *producing the objects* which appear after their action is complete. If I am an efficient cause, then they must also be efficient causes. My senses, naturally, perceive only a 'sequence' of actions on their part; *my reason*, however, demands that if my actions were the efficient causes of definite effects, their actions must be adjudged to partake of the same nature. And the same principle applies to all actions performed by others. Any other conclusion would be illogical.

On identical grounds, reason demands that we admit productive activities *in the world at large*. Plants and animals come into existence, live for a while, and die. Mechanical motion originates in bodies, and then it ceases to exist. Physical and chemical changes occur incessantly throughout the universe. These are *new realities*. These new realities must be accounted for; they cannot originate from 'nothing,' because 'nothing' cannot account for anything. Since these new realities did not exist always and do exist now, they must have *received existence*; and if they

have received existence, they must have received it from some other being in nature. But to be brought from nonexistence to existence by some other being, means that this other being gave it existence through some *positive action*; because, if this being had performed no action, nothing would have happened to bring about the existence of the new reality. Now, to bring a being from nonexistence to existence by means of a positive action, means to exert a positive influence in the production of that thing. And that is what we mean by 'efficient causality.' Consequently, *efficient causality exists* as a fact in the universe.

We thus see that the concept of 'efficient causality' is not an idle speculation or the figment of a vivid imagination, but a fact of nature.

THE CONCEPT OF FINAL CAUSE

By a 'final cause' we understand that *for the sake of which* an efficient cause acts; the *end* or *purpose*, which induces and prompts the agent to act and determines the kind and the manner of action, so that the end or purpose may be achieved and realized. When a man 'intends' to build a home, he gives the architect an idea of what kind of home he wants; the architect draws up the plans and specifications; the contractor collects the materials and puts his builders to work; the builders construct the house according to plans and specifications; eventually the house is completed and turned over to the owner for habitation. From start to finish, this chain of events was dominated and determined by the original 'end' or 'purpose' of the owner

‘to build himself a home.’ That the end or purpose was a positive influence in the production of the building, is obvious. Had he intended to construct a factory or store or service station or museum or library, the entire course of events would have been altered accordingly, suiting the action to the end or purpose intended.

The concept of the ‘final cause’ will become clearer when we consider the *main classes* of final causes.

Intrinsic and Extrinsic Final Causes. Final causes are *intrinsic*, if the action producing a definite effect is the result of a being’s *natural tendencies*. The growth and structural development of a plant from the seed to full maturity illustrates the point of a ‘natural tendency.’ The germ cell of the plant has a very definite direction in its developmental action, and this action proceeds from the powers inherent in the seed itself. External agencies, such as light, heat, moisture, soil, etc., also play their part in the growth and development of the plant; but the actual growing and the actual developing is determined by the vital constitution of the plant alone, and this is a ‘natural tendency’ inherent in the plant. Provided, then, we have here a case of ‘final cause,’ so that the plant really ‘tends’ to carry out a definite ‘plan’ of growth and development, we must say that this is an instance of an ‘intrinsic final cause.’ Final causes are *extrinsic*, when their causality is *impressed* upon them by some *outside directive force*. When a hunter for example, shoots at a deer, the bullet ‘tends’ to speed in the direction of the animal and penetrate its body; if the aim is accurate, the result will be attained. Obviously, however, this tendency on the part of the bullet is not due

to the nature of the bullet itself, because bullets have no 'natural tendency' to kill deer; it is the result of an outside directive force impressed upon the bullet by the rifle and the hunter. This is a case of 'extrinsic final causality.'

Besides this very general classification, final causes are also classified according to the *different ends or purposes* present in the productive activity of the agents. Each end or purpose designates a different type of final cause.

The 'End Which' and the 'End for Which.' The *end which* is the *good itself* which is striven for as the end or purpose to be realized through the action. For example, when a man goes about building a house, it is the house itself that is the 'end which' he strives for. The *end for which* (or *whom*) is the *thing* or *person* that is to benefit by the realization of the 'end which' is intended. When a man builds a house as a home for his family, that purpose is the 'end for which' the house is built.

Proximate End and Remote End. An end will be the *proximate end*, if it is referred to some ulterior end, but has no other end referred to itself. An end will be a *remote end*, if one or more other ends are referred to it. And this remote end will be either an 'intermediate' or an 'ultimate' end. It will be *intermediate*, if one or more ends are referred to it, and it is itself referred to some ulterior end. It will be *ultimate* if it has one or more ends referred to itself, while it is not itself referred to some other end. This ultimate end will be *relatively ultimate*, when it is the last purpose in a series of purposes in some particular line, and it will be *absolutely ultimate*, when it is the last purpose of all purposes in any line, so that no ulterior purpose or end can

be conceived. To take the example of the builder of a house. The immediate or 'proximate' purpose of building is the complete house itself. But he builds it so that his family may have a comfortable home (remote, intermediate end) and thereby enjoy earthly happiness (remote, relatively ultimate end for his family), while he himself thereby fulfills his duty as a father and husband (remote, relatively ultimate end for himself); and all this he does for the greater glory of his Creator (remote, absolutely ultimate end).

Primary End and Secondary End. The *primary* or principal end is the main one among two or more which actuates an agent and is sufficient of itself to induce the agent to act. Thus, the primary end of a man building a house may be the comfort of his family. The *secondary* or accessory end is one which is intended together with a primary end, without, however, exerting the same potent influence on the action of the agent. The builder, for example, may also be prompted by his dislike for paying rent.

End of the Act and End of the Agent. The end of the act is the purpose which is present in the act itself and which the act tends to realize because it is this particular kind of act. The end of the agent is the end which the agent has in performing this particular act. For instance, the end of the 'act of building' is the 'house' itself, while the end of the 'agent' (builder) is the 'comfort of his family' living in the house.

THE EXISTENCE OF FINAL CAUSES

The philosophic doctrine which holds that final causes are operative in nature, that things act according to a definite purpose or design, is called the doctrine of *finality*, or *teleology* (τέλος end, purpose), or purposiveness. The doctrine which denies the existence of finality or final causes in nature, is called mechanism; it explains all occurrences in nature as being determined in a purely mechanical way, so that everything is caused by what is temporarily antecedent without having any 'tendency' to produce definite results in the future.

The *problem* revolves around the question: Do beings act *in order* to realize some definite *end* and purpose through their action? Or are there merely efficient causes operative in the world which act machinelike in producing their effects?

The teleologist admits the existence of efficient causes. He does not assert that all efficient causes in the universe act with finality at all times: even the confirmed teleologist concedes that chance happenings occur. But he does maintain that all beings, organic and inorganic, are governed, to a very great extent, by ends and purposes in their actions. The mechanist asserts that nothing but efficient causes are at work in nature, and ends and purposes play no part in natural occurrences; the concept of 'finality' is a philosophic figment, due to the 'anthropomorphizing' bent of man's mind which tends to explain all things in human terms.

Among those who *advocate* teleology in nature we find Anaxagoras, Plato, Aristotle, and all scholastics. Many scientists of prominence, for example, Copernicus, Kepler,

Newton, Darwin, Pasteur, etc., were convinced of the existence of finality in the operations of nature. Among those who *deny* that final causes operate in the universe are the ancient and modern materialists, the pantheists, and those scientists who admit nothing but mechanical determinism in nature. It is well to note, however, that scientists in general preserve a more or less negative attitude toward the problem rather than a positive antagonism. The philosopher-scientists who are positivists, agnostics, and empiricists consider teleology unacceptable, because, in their view, we cannot know anything which goes beyond the immediate data of sense perception; their denial of final causes rests, therefore, on epistemological grounds rather than on the facts themselves.

To the question: 'Do final causes exist at all, at any time, under any conditions?' the answer is emphatically and categorically:

Final causes exist in conscious operations.

In the case of *man*, the evidence is so clear, that an extended demonstration is unnecessary. We are all *intuitively aware* of the fact that we perform most of our actions with precise ends and purposes in view, and these ends and purposes determine the whole course of our actions. All the activities engaged in during a normal day are inaugurated, controlled, sustained, and completed under the influence of ends and purposes; we do things *in order* to achieve definite results. Whether a man work in an office or a garage or a factory or a store or a school; whether he be a farmer or a mechanic or a broker or an engineer or an executive; whether he drive a car or a truck

or a locomotive or a boat or an airplane; whether he play cards or golf or billiards or tennis or pingpong: in whatever he does with conscious effort, he always has a *purpose* in view which prompts him to act so as to bring about a desired end-result. The entire structure and operation of industry, business, commerce, art, labor, government, etc., is the result of a host of actions, all of which are directed and dominated by definite ends and purposes. It is only the somnambulist, or the insane, or the complete idiot, who acts without a conscious end in view. Even the mechanist, when he marshals his arguments for disproving the existence of final causes and purposes, sets a purpose for his argumentation and proceeds to bring about its realization; he proves himself to be a teleologist by his very attempt to disprove teleology. The fact is transparently clear: man *intends* to achieve definite ends and purposes and *arranges his actions* accordingly; that is teleology, without question.

We also find final causes at work among *sentiently conscious beings*. Brute animals are such beings. Study the individual actions and the life history of all the animals, from the amoeba to the whale, and note how everything is dominated and regulated according to the all-controlling purposes of the *preservation of the individual and of the species*. Millions of illustrations could be adduced to show how they act in order to achieve these great fundamental purposes. Two examples must suffice. When a cat watches at the hole in the floor with unswerving eyes, crouches with tensed muscles, chases the mouse that unwisely comes forth, pounces upon it with unsheathed claws, kills it, and then devours it, is this not done for the immediate purpose

of catching its prey and for the ultimate purpose of appeasing its hunger and sustaining its life? And when a bird flies about, seeks bits of string, feathers, straw, and twigs, brings them together to a certain tree, and then shapes them with a co-ordinated sequence of apt motions into a nest, is this not done for the immediate purpose of fashioning a place for its prospective brood and for the ultimate purpose of preserving its kind? The bird, of course, does not know that its mating will result in eggs and fledglings which will need a nest, but that is beside the point; the point is, that the bird 'intends' to build a nest and its complicated chain of actions is arranged in such an orderly manner that the end-result, a completed nest fit for breeding purposes, is definitely achieved. Animals may not (and, for that matter, do not) understand the 'rationality' of their actions, but they certainly *perceive* things, *desire* them, and *strive* for them. This is finality, or purposive action, pure and simple. Teleology, therefore, actually exists in nature, at least among conscious beings.

Most scientists are willing to admit purposiveness in such instances, especially in the case of man. They experience, however, great difficulty in recognizing finality or teleology in *unconscious* beings. They argue somewhat as follows. In order that something be done 'for a purpose,' it would seem necessary that this purpose be 'held in view' as a 'future result to be achieved.' That demands a mind of some sort, which consciously apprehends the purpose and deliberately sets about to achieve it by means of appropriate actions. Unconscious beings, however, cannot apprehend such a purpose. Consequently, their actions

cannot be purposive, and final causes are therefore excluded.

This *objection* is based on a *confusion of ideas*. The opponents confuse the 'end of the agent' with the 'end of the act.' If the 'act' is purposive in itself, what difference does it make whether the 'agent' is aware of its purposiveness or not? To postulate *a priori* (beforehand) that the action must be conscious in order to be 'purposive' is a *begging of the question*, because it is an attempt to settle the question by definition instead of by fact. Certainly, if conscious knowledge of the purpose be required in order that beings can 'act for a purpose, then unconscious beings cannot possibly 'act for a purpose. But why should it be impossible for the acts in themselves to be naturally purposive; that is to say, why should it be impossible for the Creator to have given unconscious beings a *natural tendency* to perform certain actions which, as a matter of fact, have as their goal an end-result which is to be achieved in the future at the completion of the action? Purposiveness, without doubt, does actually presuppose a knowledge of the end to be realized. If then, the actions of unconscious agents are purposive in themselves, so that they have a natural tendency to lead to definite end-results unknown to the agents, the necessary conclusion to be drawn is, that an outside intelligence has *imposed* this natural tendency upon their very *essence* and *constitution*. This would be a proof, of course, that a Supreme Intelligence exists which made their essence and constitution to be what it is and gave it definite direction of action. The Creator of all beings, of course, alone could do

this. Given, then, the existence of the Creator, the objection of the opponents is pointless. Only on the supposition that the existence of a Creator is impossible, could one argue that finality in unconscious beings is impossible. On the other hand, if the *facts in the case* prove that finality exists in unconscious beings, then these facts also prove the existence of an intelligent Creator. What do the facts show?

Finality exists in unconscious operations.

To understand the problem properly, consider an action of man which is an indubitable instance of the working of a final cause. Scrutinize, for example, the action of a watchmaker assembling a watch. What is the end and purpose of his action? To construct a mechanism which will tell the time. This purpose determines the selection of the materials he must use and the method and sequence of actions necessary to assemble all the parts in their respective positions. As his action proceeds, the timepiece gradually takes shape; eventually, it is completed, and the watchmaker's action ceases, because the construction of the timepiece, which was the purpose and goal of his action, is finished. The actual watch, it will be noted, was the first thing intended and the last thing executed: the entire sequence of activity and the appropriate selection of materials was determined by something which would be achieved only in the future as the end-result of the whole operation. In the case of the watchmaker this process was consciously apprehended and intelligently carried out; a *conscious plan and design* controlled the making of the watch. When, however, we speak of finality in unconscious operation, a *similarity of purposive action* must prevail, so

that there is *plan and design* calculated to achieve a *definite end-result* through actions *appropriate for the purpose*; but all this is done unconsciously, without the benefit of knowledge on the part of the agent. It is the 'purposiveness' of the action which constitutes the essence of a final cause, not the consciousness or unconsciousness of its finality. If, then, we find that organic or inorganic beings have a distinct, though unconscious, *tendency* to perform actions which parallel the purposive actions of man, so that they proceed planfully in every way toward a definite end-result to be achieved in the future, we must admit that (unconscious) finality also controls their actions; they are purposive actions, dominated by final causes. That, we claim, is so.

Organic activity shows abundant evidence of unconscious finality or 'purposiveness.'

The *metabolic processes* of organisms are all unconscious, even in the body of an animal or man. Yet they are carried out by a marvelous adaptation of means to an end. The process is entirely *selective* in its operation, depending on the type and condition of the organism in which it takes place. The digestive organs, for example, form a complete laboratory, arranged and equipped solely for each particular type of organism, and work with an efficiency of such a high degree that the efficiency of intelligent man in his best laboratories is, by comparison, more like that of a bungling amateur. And when, for some reason, the organs of this organic laboratory are injured, they strive to *repair* the damage with every means at their disposal, something never observed in purely mechanical

things. It is as if the cells understood the exact nature and function of every organ and structure in the body, both as an individual member and as an integral part of the whole. How strong this inherent urge or tendency of the cells is, can be seen in the case of red corpuscles. If a drop of blood is placed in a suitable medium and some of the red corpuscles happen to flow away from the drop, they immediately begin forming a protective bank; fibrin filaments then solidify the banks into a tiny pipe; white leucocytes now start their work of covering the surface with a membrane of contractile cells. And thus a bit of circulatory apparatus is formed by these corpuscles and leucocytes, through the driving power of an inherent urge and tendency residing in them. Although the action, incidentally, misses its fundamental purpose, due to the fact that the blood is no longer present in its parent organism, the essential purposiveness of the action itself, namely, the building and repair of an adequate circulatory system, is plain to see. In a similar manner, the leucocytes, when taken out of the organism and placed in suitable containers, will continue to destroy microbes. They do not understand that they, under the conditions, are not defending the parent organism against its enemies, and that shows that their action is unconscious; but they have the irrepressible urge to destroy microbes, which is their purpose as scavengers, and they carry out this purposive action even when the action is no longer necessary. This is finality of action. Such instances of purposiveness could be multiplied indefinitely.

Perhaps the most striking and most universal instance of finality in organic activity is that of *embryonic development*. it is a totally unconscious process in plant, animal, and man, yet it is the most amazing illustration of a planned and designed activity observable in nature. Growth is an unconscious operation of living tissue. It begins with one original cell and proceeds to develop into a completely mature individual. Notwithstanding the unconsciousness of the process, there is a very distinct tendency and direction in it toward a specific result which lies in the future. There is no hit-and-miss method, no blind groping for effects, no chance achievement of results. Everything is methodical procedure, scheduled operation, progressive construction. No house was ever built with such precision, efficiency, and dispatch. Somehow, the germ cell contains within itself the design of the mature *individual* of a particular *specific type*, and it *tends* to develop this type under all conditions. The individuals vary in height, size, weight, and characteristics within certain limits; but they develop according to a well-defined plan, so as to carry out the pattern of the type. This development is constant, regular, natural; it is the result of an *internal driving power* present in the germ cell and prolonged through the whole life history of the organism.

As a result of this internal principle of development, billions of cells are formed, combine together into various kinds of structural members, tissues, and organs, placed in mutual relationship as to position and function. These members, tissues, and organs have their own individual kind of activity, but they are coordinated and interdependent in such a manner that the well-being of the

organism *as a whole* is the evident purpose and tendency of all combined. The end-result planned lies altogether *in the future*, because most of the organs and structures are of no use in the embryo. The chick in the shell, for example, has no use for its eyes, ears, feet, wings, lungs, digestive apparatus, sex organs, etc.; they are made for future use, and the purpose of their construction in the embryonic stage is apparent. The individual, as Alexis Carrel aptly remarks, "is born from a cell, as if the house originated from one brick, a magic brick that would set about manufacturing other bricks. Those bricks, without waiting for the architect's drawings or the coming of the bricklayers, would assemble themselves and form the walls.

They would also metamorphose into windowpanes, roofing-slates, coal for heating, and water for the kitchen and the bathroom. An organ develops by means such as those attributed to fairies in the tales told to the children in bygone times. It is engendered by cells which, to all appearances, have a knowledge of the future edifice, and synthesize from substances contained in blood plasma the building materials and even the workers."⁴

If a house is a purposive structure, built under the influence of final causes, then the development of an organism must be the same, because it is a million times superior to the most luxurious castle in beauty, compactness, complexity, appropriateness, correctness of design, and perfection of construction. Compare a ship or submarine with a fish, an airplane with a bird, an automobile with a horse, a camera with an eye, a telephone exchange with a nervous system, a pump with a heart, a

laboratory with a digestive tract, a canal with the circulatory system, a scaffold with a skeleton, an electric control station with a brain, in fact, compare any mechanical device with a similar living structure: the products of human intelligence and ingenuity suffer tremendously in the comparison, although they are the products of conscious finality. But if these human contrivances demand purposive action in order to explain their existence and performance, the construction and functions of living structures and organism from a single cell through *inherent tendency and technique* demand purposive action as an adequate explanation. And if human inventions require intelligence in conscious activity, then the unconscious development of organisms from an embryonic cell to full maturity and to death requires an intelligence which is so much more superior to man's mind as the organisms are superior to man's mechanical products. That the cells know nothing of their purposive action, is obvious. Hence, the unconsciously purposive structures and functions of organic beings must be attributed to an extraneous Intelligence immensely more perfect than the intelligence of man; any other explanation is illogical and irrational. At any rate, the *fact of finality* in unconscious organic activity must be admitted, otherwise one does violence to the facts of nature.

In organic activity also shows abundant evidence of finality or 'purposiveness.'

We observe purposive action in the *formation of atoms* from electrons, protons, and neutrons. Electrons and protons possess opposite electric charges and tend to

attract each other; neutrons are electrically neutral and neither attract nor repel other particles. Due to these facts, one would naturally suppose that single electrons and single protons would pair off to form a neutralized single electron-proton combination and be content to remain in this condition indefinitely; and one would also naturally suppose that neutrons, being unaffected by the electric charges of electrons and protons, would remain permanently in a solitary, isolated existence, without any tendency to unite with electrons and protons. Nevertheless, we find unneutralized protons crowding together in the nucleus of the elemental atoms and unneutralized electrons swarming together at a distance from the nucleus. This is not a haphazard result which is achieved now and then at random. On the contrary, these particles have a *natural tendency* and an *irrepressible urge* to unite into *definite atomic constellations* of various *specific types* which we call the *elements*. While man, through bombardment, can break up these combinations, it requires an enormous expenditure of energy to do so. This shows, that these combinations are natural, because the atoms of the elements resist dissolution to the utmost and strive to retain their integrity and individuality at all cost. When *ionization* occurs, so that orbital electrons are detached from an atom, the atom invariably seeks to capture stray electrons in order to complete the system. The atom of each element has a *typical structure and design*, resulting in properties and activities which are specifically characteristic of the element. Even in the spontaneous disintegration of radioactive elements, the entire procedure runs according

to a *planned schedule* which nothing can alter, determined by the inner constitution of the atom itself, so that each step of the process can be predicted with accuracy. We thus see that the ultimate particles throughout the universe *aim at definite end-results*, and these end-results determine their activity in all phases.

This is also true of the reactions in *chemical compounds*. No doubt, it is often accidental that elements come into contact with other elements. Once the contact is made, however, their behavior is no longer accidental, but determined by the *laws of affinity*. Elements display an unmistakable tendency to make certain combinations and reject others. Peculiar in this respect is the fact that a definite *preference* is noticeable among the elements. Even though, for example, two distinct elements would complete the octet in the outermost electronic orbit, thus producing a neutralized electric system, the atom will invariably select one of the elements in preference to the other, even displacing the one already in the compound. In all cases of chemical combinations a very definite trend is present, so that chemists can always predict the end-result. Similarly, in *crystallization* there exists an urge or tendency for all the molecules to arrange themselves according to a *planned pattern* of geometric design, and the whole process is natural, constant, and permanent.

All this leads to the inevitable conclusion, that all beings are governed, to a very great extent, by finality in their activities. Final causes are operative everywhere in nature. This striving to produce specified end-results proceeds from the *inner nature* of the agents themselves and not from

external compulsion. This world, therefore, is a teleological world, and it is a natural phenomenon. If we seek the *ultimate reason* for the marvelous finality exhibited by all beings in the organic and inorganic world, then, indeed, the explanation cannot be found in the things themselves, because they do not understand the finality of their actions, but in the *Creator*.

NATURAL LAWS AND MIRACLES

By a *natural law* we understand the rule or *norm* according to which a being is *induced to perform an action or to refrain from an action*. In its original meaning, the term 'law' is applied to the rule or norm which governs the free actions of an intelligent being; but in a wider sense, the term is applied to any imposed norm of action, and in this sense irrational and nonliving beings are also said to be governed by 'laws.' Such laws in a wider sense are the 'natural laws' or 'laws of nature. We thus speak of the Law of Gravity, the Law of the Conservation of Energy, the Law of Biological Origin, and so forth. Proximately, we mean by a 'natural law' the *constant and uniform activity* of a being; fundamentally, we mean thereby the *natural and inherent tendency* of a being to act in a constant and uniform manner.

The exact *sciences* are witnesses to the fact that the activities occurring in nature are governed by laws. It is the distinctive function of science to penetrate the apparently chaotic jumble of phenomena and discover the laws which express the cause-and-effect relations existing in the

manifold operations of physical beings. To be able to formulate these laws in words, is one of the great achievements of science.

Because of the knowledge of these laws, scientists are capable of *predicting* accurately the behavior of things under given conditions.

When objects act *constantly and uniformly* under the same set of circumstances, this cannot be due to chance, but to law. Chance-occurrences, precisely because they are not subject to law, cannot be predicted with any degree of certainty; they are neither constant nor uniform in operation and are always an exceptional event. In 1939 it happened in Berkeley, California, that in a game of bridge a perfect hand was dealt to each of the four players; one had all spades, another all hearts, another all diamonds, and the fourth all clubs. Statisticians estimate that the probability of four such hands being dealt is one in 158,000,000,000 deals. And yet the number of cards is relatively small, only 52. When, therefore, we observe the events of nature occurring with unswerving regularity, we are forced to the conclusion that they are governed by exact laws and not by the vagaries of chance.

And that is to be expected. The activities of things proceed from inherent *tendencies* present in them, and these tendencies, in turn, are grounded in the essence of things. Since the essence of things is a constant and uniform reality, it is a natural consequence that these tendencies and activities will also be constant and uniform. Concretely, therefore, the essence or nature of things is the

ultimate natural ground or reason why physical beings act constantly and uniformly according to a strict norm or law.

Some scientists consider a 'physical law' to be nothing more than a *convenient formula*. They give it only provisional value, and they base their argument on the fact that such a 'law' is the result of an *incomplete inductive enumeration*. Because of this incomplete enumeration, they say, we can never be certain that the 'law' holds for all times, or for all places, or for all conditions. Thus, the 'law' states that 'water will freeze at sea level at +32° F.' However, the amount of water which was actually frozen in this manner is infinitesimally small, compared to the amount of water that was never frozen; hence, we cannot be certain that the 'law' has universal application. These scientists are in error. Once we know the 'nature' of water, we also know that water is always and everywhere the same. Since the 'nature' of water is what it is, it must act in the same manner always and everywhere; consequently, it will always freeze at sea level at + 32° F. A complete inductive enumeration, therefore, is unnecessary for the establishment of a universal physical law. It is true, of course, that we are unable to understand the essence of physical things completely; but that is a proof of the limitation of our knowledge, and not a valid proof against the constancy and uniformity of creatural activity.

We speak of natural laws as being *necessary laws*. They are necessary in the sense that physical objects are determined by their very nature and essence to act or not to act as they do, and they have no choice in the matter. This necessity, however, is not absolute, but *contingent*. The

laws governing the physical operations occurring in the universe are dependent on the natural tendencies inherent in the beings themselves. Only under the supposition that these beings themselves are absolutely necessary both in their essence and existence, would it be correct to state that the laws of nature are absolutely necessary. No one, however, can prove that the universe and the objects comprising it are absolutely necessary in their essence and existence. On the contrary, many beings, especially all organisms, come into existence and pass out of existence; chemical compounds are made and unmade continuously. Hence, they are contingent, and the laws governing them can only be contingently necessary. As a matter of fact, all beings were created by the Supreme Being, and it was He who gave them their essence and with it the laws determining their activities. Consequently, all the *laws of nature* are only *contingently necessary*, depending entirely on the will of the Creator.

From this it follows that the Creator can, if He so desires, suspend the effects of the laws of nature at any time, either entirely or in part; He can make exceptions to the general laws in individual cases at will. Since He made the natural laws, He can also abrogate them. Now, any *perceptible event*, forming an *exception* to the regular course of nature and produced by *divine intervention*, is a *miracle*. Miracles, therefore, are *possible*. To deny the possibility of miracles is equivalent to denying God's power over His own handiwork, which is absurd. Whether miracles have ever actually occurred, is a matter of historical evidence and lies outside the purview of philosophy. Philosophy is concerned with the

problem of the possibility of miracles, and that cannot consistently be denied.

The complete subjection of all things in the world to law and order in their efficient causality and the all-encompassing dominance of final causality over physical bodies and their activities, clearly indicates that the origin of organic and inorganic beings lies not in themselves but in a Supreme Lawgiver who imposed His will upon them.

SUMMARY OF CHAPTER XVII

By *causality* we understand the positive influence of one thing in the production of another. There are *four main types of causes: material, formal, efficient, and final*. Here we are concerned with efficient and final causes.

1. *Concept of Efficient Cause*. An 'efficient cause' is one 'by which' an effect is produced; it is an agent which by its positive action produces something. The main *classes* of efficient causes are: First cause and second cause, physical and moral cause, principal and instrumental cause, cause *per se* and cause *per accidens*, proximate and remote cause, total and partial cause, necessary and free cause.

2. *The Existence of Efficient Causes*. Experience proves the existence of efficient causality. Our 'internal experience' proves that our mental operations are produced in us and by us. Our 'external experience' proves that we are the producing agents of many external effects.

Reason demands efficient causality in nature. When we observe other human beings producing things which we know to be instances of efficient causality in our own actions, we must conclude that they, too, are efficient causes. On identical grounds, reason demands that we admit productive activities in the world at large. New realities constantly come into existence, e.g., organic beings and chemical compounds. Since they cannot originate from nothing, they must be 'produced.'

3. *The Concept of Final Cause*. A final cause is one 'for the sake of which' an efficient cause acts in producing

something. There are many classes of final causes. Besides the general classification of 'intrinsic' and 'extrinsic' final causes, we classify final causes according to the *ends* or *purposes* which may actuate an efficient cause: the 'end which' and the 'end for which,' proximate and remote end, primary and secondary end, the end of the act and the end of the agent.

4. *The Existence of Final Causes.* Teleology, the doctrine of final causes, is opposed to mechanism, the doctrine which explains all natural occurrences in a purely mechanical way. The *problem* is: Do beings act 'in order to' realize some definite 'end' and 'purpose' through their action?

Final causes exist in *conscious operations*. Our own consciousness testifies to the fact that we almost invariably act with a purpose in view; we intend certain results and arrange our actions in an intelligent manner to achieve these results. *Sentiently* conscious beings, namely, brute animals, are governed in their actions by the all-controlling purposes of the preservation of the individual and of the species; they perceive things, desire them, and strive for them.

Final causes also exist in *unconscious operations*. They act according to a plan and design calculated to achieve a definite end-result through actions appropriate for the purpose. *Organic* activity manifests purposiveness in the metabolic processes and in embryonic development. *Inorganic* activity manifests finality in the formation of atoms, in the typical structure and design of the elements, in chemical compounds, and in crystallization.

5. *Natural Law and Miracles.* By *natural law* we understand the rule or norm according to which a being is induced to perform an action or to refrain from an action.

The exact *sciences* are witnesses to the fact that the activities occurring in nature are governed by laws. Things are so *constant and uniform* in their activities, that scientists can predict the course of events with accuracy; chance effects are haphazard and exceptional. This constancy and uniformity is based on the internal constitution and *essence* of the things themselves, the latter giving rise to *specific tendencies* of action.

Physical laws are *necessary* laws, but only *contingently*, not absolutely, necessary. This is due to the fact that physical beings are themselves contingent, because they are created; they are dependent on the will of the Creator.

It follows that the Creator can suspend the effects of the laws of nature or make exceptions in individual cases. When this happens, a *miracle* occurs, which is a perceptible event, forming an exception to the regular course of nature and produced by divine intervention. Hence, miracles are *possible*.

Chapter 18

RELATIVITY

PERHAPS THE MOST CONTROVERSIAL ISSUE BEFORE THE MINDS of present-day thinkers is Einstein's *Theory of Relativity*. It is so complicated in its mathematical calculations and so vast in its scope, that only experts in mathematical physics are capable of following the theory through all its ramifications and intricacies. It is primarily a theory of *physics*, not of metaphysics. However, certain phases of the Theory of Relativity involve metaphysical concepts, and the cosmological implications interest the philosopher.

While it is practically impossible to give an adequate exposition of the theory in the short space at our disposal, a summary of its leading ideas and a critical evaluation of some of its features will be attempted.

ORIGIN OF THE THEORY

The Theory of Relativity has its origin in the *problem of motion*. The problem arose largely in connection with celestial mechanics. *Tycho Brahe* (1546—1601), without the aid of a telescope, made an exhaustive study of the movements of the planets. He did not possess the key to the

proper understanding of these movements, because he viewed them from the standpoint of the earth. *John Kepler* (1571—1630), his pupil and assistant, discovered the key; viewed from the standpoint of the sun, these complicated movements resolved themselves into regular ellipses around the sun. One great problem of astronomy was thus solved when Kepler expressed the data of his master in three simple descriptive laws. He, however, did not understand why the planets move in such ellipses.

Galileo Galilei (1564—1642) discovered the laws of terrestrial dynamics through a study of falling bodies. He found that all bodies, whether heavy or light, fall to the ground in the same way, their velocity increasing by about 32 feet per second in every second. *Isaac Newton* (1642—1727) combined the ideas of Kepler and Galileo in a grand synthesis. Studying the movements of the planets, as expressed in Kepler's laws, he found that the acceleration of a planet depends on the distance of the planet from the sun, and its acceleration diminishes as the distance increases according to the law of the inverse square. In other words, planets have a tendency to fall toward the sun, just as bodies have a tendency to fall toward the earth; *gravitation* regulates the movements of the planets. In formulating his *Laws of Motion*, Newton enunciated the fact that a change or *acceleration* of motion demands an outside impressed force; motion itself, once started, goes on indefinitely in a straight line. Newton intended his laws to be merely descriptive formulations. Still, at times he turned philosopher and philosophized on the concepts of 'time,' 'space,' and 'motion.'

Newton distinguished between *absolute* time, space, and motion and *relative* time, space, and motion. By 'absolute time' he meant duration, or the persistent existence of things; and that, he says, cannot be changed, but is always the same, whether motions be swift or slow or null. He admitted that, perhaps, there is no equable motion by which time can accurately be measured; hence, our ordinary measurements of time are relative to some particular motion and are therefore more or less inaccurate. Similarly, in common affairs we use relative places and motions, measuring them against other places and motions. 'Absolute place' would be the place of a body which is altogether at rest with respect to absolute space in general, and 'absolute motion' would be the motion of a body in reference to a body or set of bodies in absolute rest. He claims that in physical disquisitions we should abstract from the senses and seek to measure places and motions according to absolute standards; again, however, he admitted that it may be impossible to find any body absolutely at rest, which could serve as a fixed point in the universe from which absolute standards of time, space, and motion might be taken.

Here we have the *crux of the problem* which eventually gave rise to the Theory of Relativity. An example will illustrate the difficulty of accurate measurement. I am traveling, let us say, in a straight line toward the north at a speed of 50 miles an hour. But relative to what am I traveling in this manner? Relative to the earth; the earth is my fixed point or *frame of reference* (post of observation). The earth, however, has a rotational motion, which twists

my movement over its surface from a straight line into a curved line; and, since the earth moves at a rate of approximately 100,000 miles an hour around the sun, I am really moving much faster than 50 miles an hour, relative to the sun, and the elliptic path of the earth gives an additional curvature to my actual motion. The entire solar system is also in motion toward some point in the universe, and this also influences my velocity and my line of motion. A further complication arises from the fact that the entire galaxy of the Milky Way also moves. Viewed, then, from the different 'frames of reference' — earth, sun, solar system, Milky Way, and the universe at large — my simple journey becomes a very intricate affair of velocity and curved motion. We have now a number of 'relative motions,' motions 'relative' to some particular frame of reference; but what is my *absolute motion*, measured according to the absolute standard of distance from some body or system in the universe which is absolutely at rest? Is there such a body or system? Can we discover any fixed point as an *absolute frame of reference*? If not, all our measurements of time, space, and motion are only 'relative.' To put the matter concretely: When I travel 50 miles an hour straight north, relative to the earth as my frame of reference, what is my absolute velocity, time, and direction of movement, gauged by the absolute standards of measurement derived from a body or system absolutely at rest in the universe?

Newton himself thought he had found the motionless frame of reference in the *fixed stars*. Subsequent discoveries, however, have shown that these stars in the celestial constellations are not 'fixed' in the sense indicated.

So far as we know, all are in motion relative to one another. Later scientists hoped to find the absolute standard of rest in the *aether*. Hence, if the motion of a body relative to the aether could be determined, they felt that the motion of this body, for example, of the earth in its revolution around the sun, could be measured in absolute units; that accomplished, the absolute motion and position of the other heavenly bodies could also be calculated. A number of experiments were made along these lines. Most famous among these were the experiments of *A. Michelson* and *E. W. Morley* in 1881.

The Michelson-Morley experiment was designed so as to determine the velocity of the apparatus, and thereby also of the earth, in the supposedly fixed aether. It was based on the velocity of light. A ray of light was directed onto a half-silvered mirror, placed at an angle of 45° to the beam. Half of the beam went through the un-silvered portion and traveled on in a straight line, while the second half was reflected in a direction at right angles to the first half. The two half-beams were reflected back and forth by mirrors placed at equal distances, were rejoined, and then compared. If there was any difference of velocity in the two directions, the phenomenon of interference should appear; otherwise, the two rays should be in phase. There should be a difference in this velocity, if the apparatus (and the earth) is moving in the same direction as the light; there should, of course, be no difference, if the apparatus (and the earth) is at rest. In the first case there would be a time-lag, and in the second case there would be none; this time-lag would produce a difference of phase and cause interference. As

the apparatus is turned, or as the earth reverses its course during its annual revolution, this difference of phase should be noticeable and measurable. As a matter of fact, however, the results were rather negative; the experiment failed to manifest the expected velocity through the aether. The experiments were repeated in 1904 and 1905 by E. W. Morley and Dayton Miller, and by Miller again in 1921, and thousands of experiments were made between 1921 and 1925. The results were divergent. They did show a definite 'aether-wind' or 'aether-drift,' estimated at between 5 and 10 kilometers per second. Even in the Michelson-Morley experiments the results were never null; but they were unsatisfactory and generally overlooked or ignored.

Scientists were at a loss to explain the apparently negative results of the experiments; they should have been positive, if the earth really moves through the stationary aether. It was unthinkable to return to the ptolemaic world system, in which the earth occupied the center of the universe and was absolutely at rest. Then how explain the paradox? *Fitzgerald* and *Lorentz* now came forward with a daring hypothesis. If we assume, they said, that every body suffers a *contraction* of length in the direction of its motion while passing through the aether, the absence of a measurable aether-drift is explained. This contraction would affect all measuring rods, clocks, and also the apparatus of Michelson and Morley. Provided this contraction is sufficient in amount to compensate for the difference in length of the two half-beams of light, the time-lag would be eliminated, and the time of passage would be the same for both half-beams traversing the two paths.

Under such conditions an aether-drift could neither be detected nor measured. This accounts for the negative result of the experiments designed to discover and measure the velocity of the earth in reference to the 'fixed aether.' It must, therefore, be assumed that it is impossible for us to determine a frame of reference which is absolutely at rest. To all appearance, then, the only available standards of measurement are 'relative' standards; 'absolute' standards for measuring time, space, and motion are unavailable.

It was at this point that *Albert Einstein* stepped to the fore with his *Theory of Relativity* in 1905.

THE SPECIAL THEORY OF RELATIVITY

The notion that our measurement of observed motion is, to a great extent, 'relative,' is nothing new. Newton was explicit on the point. Einstein deserves the credit of having developed the principle into a complete system embracing the whole world, from electromagnetic phenomena of atomic dimensions to physical events of astronomical proportions.

We are dealing with *observable local motion*, and that, Einstein says, has only a 'relative,' not an 'absolute' meaning. This is clear from the fact that, whenever we attempt to determine and measure 'motion,' 'direction of motion,' and 'rest,' we can do this only by comparison with some other body as a frame of reference. The values change as the frame of reference changes. Let us suppose a train is moving past an embankment at the rate of 50 miles an hour. A passenger leans out of the window and drops a

pebble to the ground. Is the path of the pebble straight or curved? The passenger would see it as a straight line; an observer on the embankment would see it as a parabola. Both are right, because each has a different frame of reference; the passenger views the pebble from the frame of reference of his train, while the other observer views it from the frame of reference of the embankment. Similarly, if the passenger walks toward the head of the train with a speed of 3 miles per hour, one can say that he is traveling 3 miles per hour or 53 miles per hour, depending on the fact whether one takes the train or the earth as the frame of reference. So, too, it is impossible, from the *mere observation* of two trains, to determine which of the two is in motion and which is at rest, provided the observer has no fixed point (e.g., the surrounding landscape) from which to reckon; the phenomenon of motion is the same under either supposition. So long as we cannot discover any fixed, motionless frame of reference for the universe as a whole, it is obvious that we cannot assign any absolutely valid determinations of place and motion for bodies moving in space, except those which are relative to these observable bodies. The *law of inertia*, formulated by Newton and based on the mechanics of Galileo, postulates that a body, which is sufficiently removed from other bodies so as not to be affected by them, will continue in a state of rest or of uniform motion in a straight line. This law gives us the system of co-ordinates or reference bodies to be employed in mechanical description. It applies to *inertial systems*, not to systems having a rotational or accelerated motion, because to an observer on a rotating or accelerated system

the straight line of the inertial system would appear circular or curvilinear.

When, therefore, we have two co-ordinate systems, K and K' , both of which are moving uniformly in a straight line with respect to each other, then any mass which has a uniform translatory motion relative to K will also have a uniform translatory motion relative to a second coordinate system K' . In such a situation the general laws governing natural phenomena are identical for both co-ordinate systems, K and K' . This is the *principle of relativity* in a restricted sense.

Einstein applied this principle to the propagation of light. Light moves in a vacuum in a straight line with a velocity c 300,000 kilometers per second (approximately 186,000 miles). It is the same for all colors. De Sitter, from observations on double stars, showed that this velocity was *independent of the velocity* of motion of the radiant body. This, however, involves serious difficulties, when viewed from the standpoint of classical physics. When one body is at rest and another in motion in the same direction as the light, it should take the light longer to reach the body in motion. The Michelson-Morley experiments showed that there was no evidence of time-lag. Fitzgerald and Lorentz explained this by means of the contraction of moving bodies. Einstein, in accord with the principle of relativity, made a far more fundamental assumption. In his view, since the Michelson effect was null in the inertial system in motion and in the system at rest, it was necessary to assume that aether-drift has no observable influence of any kind on the velocity of light; the measured velocity is the

same in both instances. The medium of transmission can have no effect on the optical and electromagnetic phenomena. Such a medium, therefore, is superfluous. This is Einstein's *postulate of the constancy of light*.

According to Einstein, nature is so constituted in its phenomena and laws, that it is impossible to demonstrate the existence of absolute motion. The newtonian concept of 'absolute space and 'absolute time' is meaningless. The concepts of 'space' and 'time' must be recast and reconstructed to fit the conditions of relativity. There are any number of different systems of space and time, all equivalent in value, depending on the particular inertial systems in which they are found; and every inertial system can consider its own space and time to be the true space and time.

Events are said to occur in time. The term 'time' involves the concepts of *succession* and *simultaneity*. When events succeed each other in time, the one is 'before' and the other is 'after.' When events occur at the same moment, they are said to be 'simultaneous.' The physicist demands that 'time' be reduced to the quantitative measurements of a clock. It is usual to consider the 'time' of an event independent of distance and velocity, possessing a value of its own; no matter how fast or slow things move, the time is the same for all things, whether at rest or in motion, whether with reference to the earth or to the stars. If this were so, time would have an absolute value. The postulate of the constancy of light, however, shows that the concepts of 'succession' and 'simultaneity' have only relative value. For example, if two lights are flashed a mile apart toward

an observer who is midway between the two points, and he himself is stationary, he will see them simultaneously, provided they are flashed at the same moment according to the readings of a clock. But if a second observer is traveling on a speeding train parallel to the path of this light, the second observer will meet the ray coming from one point and recede from the ray coming from the other point, so that the first ray is shortened toward him and the second ray is lengthened; in consequence of this, he will see the one flash earlier than the other, even though he be midway between the two points. It follows that an event may be simultaneous for one frame of reference and not simultaneous, but successive, for another frame of reference. The reverse, of course, is also true; what would appear 'simultaneous' to an observer on a moving frame of reference, would be 'successive' to an observer on a stationary frame of reference. On similar grounds, events happening in the stars may appear to a terrestrial observer to be simultaneous, although these events, due to the difference of distances from the earth, are really in the relation of 'before' and 'after,' the one happening earlier than the other. It will even occur that a 'past' event in the stars, viewed from the earth, will follow some other event and thus appear to be 'future' to it, thus reversing the order of time. Every reference system, therefore, has its own 'time,' and 'time,' together with 'simultaneity' and 'succession,' becomes meaningless, unless we know the reference system to which it applies. This is the *relativity of time*.

The same line of reasoning applies to the measurement of *lengths* and *distances*. They have no absolute values; their values are relative to the different frames of reference. The lengths of moving bodies are contracted or shortened in the linear direction of their motion. Fitzgerald and Lorentz used this principle to explain the negative results of the Michelson-Morley and similar experiments. Einstein accepts the principle of contraction; he finds the reason for it, however, not in the motion itself, but in the motion relative to the chosen body of reference. Thus, the mirror system of the Michelson-Morley experiment was contracted or shortened for a co-ordinate system at rest with respect to the sun, but not for a co-ordinate system which moves with the earth. This explanation is in accordance with the principles of relativity and is more satisfactory. Hence, a body at rest, when measured, will be longer than a body in motion, and the contraction of a body in motion will become greater as the speed increases; however, it is only at high velocities that this contraction is noticeable and measurable. Motion affects all measuring rods and clocks; a clock, for example, will go faster in a reference system at rest than in one which is in motion.

It follows, that 'space' and 'time' are relative to a definite system of co-ordinates or frame of reference and depend upon the standpoint of the observer and the velocity of the system with respect to the observer. This is Einstein's *Special, or Restricted, Theory of Relativity*, and it is based on two *postulates*. The *first* reads: When two systems move with a uniform linear velocity relative to each other, observers in either system, by observation and

measurement of phenomena in the other, cannot learn anything more about the motion than the fact that there is this relative motion. The *second* reads: Measurements of the velocity of light in either system will always give the same numerical value, no matter what the position of the source of light happens to be; in a vacuum the speed of light is constant.

The *consequences* of the application of this theory and its principles on physics are manifold and far reaching. The *inertia* of a body is not constant; measured from the standpoint of the earth, inertia increases and decreases with velocity. The Inertia of a moving body even varies according to different directions relative to motion; at right angles to the direction of motion the variation is less, and more in the direction of the motion itself. It follows from this that the *physical mass* of a body also varies with motion. If we call the mass of a body 'lying in the direction of its motion its 'longitudinal' mass and the mass lying transverse to this direction its 'transversal' mass, then its 'longitudinal mass' increases with the increase of motion and is greater than the 'transversal mass.' In fact, the longitudinal mass increases proportionately as it approaches the velocity of light; and this mass would be infinite, if it could ever retain the velocity of light. The principles of relativity also apply to all electrical and magnetic phenomena, to sound, color, etc., because of the motions and measurements involved. In virtue of this relativity, there are only a few physical constants available for the accurate description of the universe: the velocity of the propagation of light in a vacuum, Planck's quantum of action, the electrical charge

on an electron, the mass of an electron while at rest, and perhaps a few more.

THE GENERAL THEORY OF RELATIVITY

The Special, or Restricted, Theory of Relativity applies only to inertial systems. Under the sole influence of inertia a body will remain in a state of rest or, if it be in motion, will move with a uniform speed in a straight line. A change of the velocity of a moving body, as regards either its speed or direction or both, is termed *acceleration*. Hence, any body passing from rest to motion or from motion to rest, or whose motion is increased or retarded, or whose direction of motion is altered in any manner, is said to be subject to 'acceleration.' According to Newton's Second Law of Motion, it takes a *force* to produce such a change, and this force is measured by the product of the body's inertia by the acceleration produced.

In 1915 Einstein published his *General Theory of Relativity*. There are very few, if any, instances of inertial motion among the natural occurrences of the universe; all, or practically all, belong to the class of accelerated motions. It was the purpose of the General Theory to apply the principles of relativity to accelerated motions. According to the principle underlying the Special Theory of Relativity, two reference-bodies, the one at rest (K) and the other in a uniform rectilinear motion (K') are equivalent to each other, so that, in the physical description of natural events, the general laws of nature have the same form in both. This principle enunciates the physical relativity of all *uniform*

motion. In a broad way, the *general* principle of relativity, as extended to include non-uniform motion, may be worded to read: All reference-bodies (K , K' , etc.) are equivalent for the formulation of the general laws of nature, or description of natural processes, *irrespective of the character of their motion*. The principle, therefore, applies also to reference-bodies in *rotating* or *curvilinear* motion.

In classical physics the description of the scene of an event and of the position of a body in space was based on the designation of some point of reference on a rigid body. Measurements were made by using the cartesian system of co-ordinates, namely, three plane surfaces perpendicular to each other and rigidly fixed to a rigid body. The *cartesian* co-ordinate system presupposes the validity of euclidean geometry and has value only for a euclidean continuum of three dimensions. Now, it is not always possible to use rigid reference-bodies in the space-time description of events or positions, and thus the cartesian system of co-ordinates will not be adequate under all conditions. We must substitute the *gaussian* system of curves for the cartesian system, because the gaussian system can be applied to a continuum of any number of dimensions and not merely to a euclidean continuum of three dimensions. The general principle of relativity then receives the following expression: All gaussian co-ordinate systems are essentially equivalent for the formulation of the general laws of nature. The special theory of relativity has validity only for inertial reference bodies uninfluenced by a gravitational field. As a matter of fact, however, all moving bodies are subject to the influence of a *gravitational field*, and that means *accelerated* motion.

Even clocks are affected in this manner, and that involves changes in their indication of time, which is an important item in all physical description of events. The Special Theory of Relativity must, therefore, be expanded into a General Theory of Relativity.

In applying the general principle of relativity to the effects of a gravitational field, Einstein combined the concepts of *inertia* and *gravitation* in a remarkable synthesis and subjected both to relativity. In this manner he attempted to arrive at a better understanding and a more adequate explanation of the working of gravitation. He was led to this synthesis by the fact that physics measures the inertia of a body by its weight. Science never has been capable of explaining why all bodies of whatever mass fall with the same speed of acceleration in a vacuum. Einstein finds the explanation of the phenomenon in the theory that the gravitational mass of a body is equal to its inertial mass, both being the result of the accelerated motion of an inert body. This leads to Einstein's *Principle of Equivalence*: For any one particle in a gravitational field it is possible to replace the effect of the field by a mathematical transformation of axes. This means, that the effect observed upon a body by a gravitational field would appear to the observer to be the same if his reference system would acquire an acceleration equivalent to that of the body.

Einstein clarifies this principle by means of an illustration. If we imagine a large chest or box (something like the cage or compartment of an elevator) situated in space far from all appreciable masses, this chest would approximate the condition of an inertial system. If this chest

is pulled upward by an imaginary being with a constant force, it will move with a uniformly accelerated motion. This accelerated motion will be transmitted to the body of an observer isolated in the chest and to any object, say a ball, which he holds in his hand. On releasing the ball from his hand, it will be freed from the acceleration of the chest and drop to the floor with an accelerated relative motion. Whatever kind of object he releases, to the man in the chest it will appear that its acceleration is always of the same magnitude, and he will conclude that he and the chest are at rest in a gravitational field. If the man affixes a body to the free end of a rope suspended from the lid of the chest, a tension will be caused in the rope and it will assume a vertical position. The man will attribute this to the downward pull in a gravitational field and conclude that it is the *gravitational mass* of the suspended body which produces the tension. An observer, situated on another system of reference and poised freely in space, will interpret the phenomenon in an entirely different manner; he will attribute the physical phenomenon of the tension to the accelerated motion of the chest, not to a gravitational field, and conclude that it is the *inertial mass* which determines the magnitude of the tension. This proves the relativity law of the equality of gravitational and inertial mass.

The problems of gravitation thus become subject to the general theory of the relativity of all motion, and the existence of aether as a medium becomes superfluous.

The *consequences* of the General Theory of Relativity have an important bearing on the doctrine of light. The

behavior of light will be different in a galilean inertial reference-system and in an accelerated gravitational reference-system. In the galilean reference-system K , light will travel rectilinearly with a velocity c ; here the velocity, for instance, on the surface of the earth is constant. But in an accelerated gravitational field the rays of light will be propagated *curvilinearly*. Einstein estimated, and predicted, that the magnitude of the curvature of light rays, when passing very close to the sun, should be 1.7 seconds of arc. Subsequent observations, made during solar eclipses, substantially verified Einstein's claims, at least to the satisfaction of many scientists. A second application of the general principle of relativity was made in the development of formulas for the motion of planets, particularly with regard to the orbital motion of *Mercury*. After all allowances had been made for the gravitational factors involved, the rotation of Mercury, which is in the direction of the motion of the planet, could not be accounted for by classical physics by an amount equal to 43 seconds of arc per century. Newton's laws failed to explain the phenomenon. By means of relativity equations Einstein succeeded in determining the true rate of rotation to within one second of arc per century. Einstein's third triumph occurred, when his prediction was verified that *light waves* would be *lengthened* in the gravitational field of the sun, and that this lengthening would vary with the respective wave lengths. For the blue light of wave length 4000\AA , he estimated that this would amount to 0.008 angstrom units. Grebe and Bachem, in 1920, claimed to have observed such a lengthening; it was equivalent to the recession of the

source of light of 0.56 kilometers per second. This means that the vibration of a light wave in the sun occurs at a rate which is slower than the rate of a light wave for a similar atom on our globe. In the eyes of many scientists, these predictions, resulting from formulas deduced from relativity equations without the aid of special assumptions, must be looked upon as strong arguments in favor of the Theory of Relativity, because Relativity succeeded where classical physics had met with failure.

THE NON-EUCLIDEAN UNIVERSE

It is a commonplace among relativists that the main features of the universe are *non-euclidean in character*; that is, they do not conform to the three dimensions of euclidean geometry. The universe must be envisioned as a *four-dimensional spacetime continuum*. In order to give us a comprehensive picture of the non-euclidean universe, A. S. Eddington¹ summarized the salient points of the theory of relativity.

1. The order of events in the external world is a four-dimensional order.

2. The observer either intuitively or deliberately constructs a system of meshes (space and time partitions) and locates the events with respect to these.

3. Although it seems to be theoretically possible to describe phenomena without reference to any mesh-system (by a catalogue of coincidences), such a description would be cumbersome. In practice, physics describes the relations of the events to our mesh-system; and all the terms of

elementary physics and of daily life refer to this relative aspect of the world.

4. Quantities like length, duration, mass, force, etc., have no absolute significance; their value will depend on the mesh-system to which they are referred. When this fact is realized, the results of modern experiments relating to changes of length of rigid bodies are no longer paradoxical.

5. There is no fundamental mesh-system. In particular problems, and more particularly in restricted regions, it may be possible to choose a mesh-system which follows more or less closely the lines of absolute structure in the world, and so simplify the phenomena which are related to it. But the world-structure is not of a kind which can be traced in an exact way by mesh-systems, and in any large region the mesh-system drawn must be considered arbitrary. In any case the systems used in current physics are arbitrary.

6. The study of the absolute structure of the world is based on the 'interval' between two events close together, which is an absolute attribute of the events independent of any mesh-system. A world-geometry is constructed by adopting the interval as the analogue of distance in ordinary geometry.

7. This world-geometry has a property unlike that of euclidean geometry in that the interval between two real events may be real or imaginary. The necessity for a real distinction, corresponding to the mathematical distinction between real and imaginary intervals, introduces us to the separation of the four- dimensional order into space and time. But this separation is not unique, and the separation

commonly adopted depends on the observer's track through the four-dimensional world.

8. The geodesic, or track of maximum or minimum interval-length between two distant events, has an absolute significance. And since no other kind of track can be defined absolutely, it is concluded that the tracks of freely moving particles are geodesics.

9. In euclidean geometry the geodesics are straight lines. It is evidently impossible to choose space and time-reckoning so that all free particles in the solar system move in straight lines. Hence, the geometry must be non-euclidean in a field of gravitation.

10. Since the tracks of particles in a gravitational field are evidently governed by some law, the possible geometrics must be limited to certain types.

11. The limitation concerns the absolute structure of the world, and must be independent of the choice of the mesh-system. This narrows down the possible discriminating characters. Practically the only reasonable suggestion is that the world must (in empty space) be 'curved no higher than the first degree'; and this is taken as the law of gravitation.

12. The simplest type of hummock with this limited curvature has been investigated.² It has a kind of infinite chimney at the summit, which we must suppose cut out and filled up with a region where this law is not obeyed, i.e., with a particle of matter.

13. The tracks of the geodesics on the hummock are such as to give a very close accordance with the tracks computed by Newton's law of gravitation. The slight

differences from the newtonian law have been experimentally verified by the motion of Mercury and the deflection of light.

14. The hummock might very properly be described as a ridge extending linearly. Since the interval-length along it is real or time-like, the ridge can be taken as a time-direction. Matter has thus a continued existence in time. Further, in order to conform with the law, a small ridge must always follow a geodesic in a general field of space-time, confirming the conclusion arrived at under '8'.

15. The laws of conservation of energy and momentum in mechanics can be deduced from this law of world-curvature.

16. Certain phenomena such as the Fitzgerald contraction and the variation of mass with velocity, which were formerly thought to depend on the behavior of electrical forces concerned, are now seen to be general consequences of the relativity of knowledge. That is to say, length and mass being the relations of some absolute thing to the observer's mesh-system, we can foretell how these relations will be altered when referred to another mesh-system."

As a consequence of the theory of relativity, says Eddington, "our partitions of space and time are introduced by the observer and are irrelevant to the laws of nature; and therefore the current quantities of physics, length, duration, mass, force, etc., which are relative to these partitions, are not things having an absolute significance in nature." That does not mean that there is nothing absolute in the features of the world, because "material particles and

geodesics are both features of the absolute structures of the world.”³ “The relativity theory of physics reduces everything to relations; that is to say, it is structure, not material, which counts. The structure cannot be built up without material; but the nature of the material is of no importance.”⁴ The four-dimensional world is not merely an illustration of mathematical processes. Eddington is emphatic, that “the real three-dimensional world is obsolete and must be replaced by the four-dimensional space-time with non-euclidean properties.”⁵

Eddington gives the following picture of Einstein’s world according to curved space-time. “His world is cylindrical-curved in the three space dimensions and straight in time dimension. Since time is no longer curved, the slowing of phenomena at great distances from the observer disappears. . . The radius [of the universe] is thought to be of the order 10^{13} times the distance of the earth to the sun. A ray of light from the sun would take about 1000 million years to go around the world; and after the journey the rays would converge again at the starting point, and then diverge for the next circuit. The convergent rays would have all the characteristics of a real sun so far as light and heat are concerned, only there would be no substantial body present. Thus corresponding to the sun we might see a series of ghosts [phantom suns, Author.] occupying the position where the sun was 1000, 2000, 3000, etc., million years ago. . . . Perhaps one or more of the spiral nebulae are really phantoms of our own stellar system.”⁶

This brief description of Einstein’s Theory of Relativity, stripped of its mathematical calculations, is rather

inadequate; but it should give the student an idea of its general trend and implications.

SCIENTIFIC OBSERVATIONS

What are we to think of this theory? Relativists attempt to express unusual ideas in customary terms, and the result is often confusing and sometimes misleading. We must bear in mind, however, that they must use the terms of language as they find them. It is the ideas, more than the language, which we must consider.

Viewed from the scientific standpoint, Einstein's Theory of Relativity has for its purpose a more exact formulation of the laws which govern observable phenomena of nature. This is a legitimate endeavor. How far the theory succeeds in this, is a matter of scientific investigation and verification. The final verdict rests with the physical and mathematical sciences. While many scientists have accepted the theory, it would be erroneous to think that it has been universally adopted; in fact, many prominent physicists and mathematicians refuse to subscribe to it.⁷

Even from a scientific point of view, the theory seems to rest upon a rather insecure foundation.

One of the phenomena which called forth the Theory of Relativity was the apparently negative result of the Michelson-Morley experiment. Yet, as a matter of fact, the result was, to a large extent, positive. Michelson, Morley, Miller, and Piccard estimated that an aether-drift actually occurred. How, then, can Einstein and the relativists assert so emphatically, that an aether-drift could, from the very

nature of the case, neither be measured nor detected, especially when these scientists arrived at their conclusion through practical experiments whereas Einstein arrived at his through theoretical considerations? Secondly, while the aether-drift was not as quantitatively great as expected and calculated, might this not be due in part to the imperfection of the mechanical apparatus? The surfacing of the mirrors could never be perfect, and the very motion of the molecules in the whole system should presumably have an effect upon the extremely fine waves of light, so as to interfere with completely accurate results. Finally, if we assume that aether is viscous and is carried along to a certain degree by the earth, the drift on the surface of the earth would naturally be less than at some distance from the earth; the measurements would not reach an absolute value, but only a diminished approximation. The issue does not seem definitely settled. Perhaps more refined experiments will solve the problem one way or the other. At any rate, there is a discrepancy between practical experiments and theoretical calculations which must not be overlooked or ignored. In case a real aether-drift should ever be demonstrated experimentally, the foundation of the theory of Relativity will be destroyed.

Then, too, the truth of the *postulates* of the theory are by no means self-evident. There is the postulate of the *constancy of light*. This constancy of the velocity of light (300,000 kilometers per second) is not assumed for all media; we know that it varies for gases and liquids. But it is assumed for the passage of light in a vacuum, and that irrespective of the motion of the source which emits the

rays: This is an *a priori assumption*. If light were a wave motion, then the wave would indeed go forward, no matter what the velocity of its source. Light, however, consists of photons which are material particles, and the variations in the energies of the source (e.g., the sun) might possibly bring about a variation in the velocity of the light. There is little evidence to show that this possibility must be ruled out. And if the aether exists as a medium in space, as most scientists hold, any variation in its density would in all probability affect the velocity of light to some degree, no matter how slight, so that it would not be altogether constant.

It is also a postulate of the relativity theory that motion is relative and that all *reference-systems are equivalent*. 'Absolute motion' is meaningless, because it is impossible to determine any fixed points in the universe from which the measurements of absolute distances and motions could be made. This is, of course, a *practical* difficulty, originating in the meagerness of our knowledge of the universe. But that is by no means a positive proof that such fixed points do not exist. There might be cosmic bodies or cosmic centers which are stationary and could serve as the guiding points for the measurement of absolute distances and velocity. The fact that we do not, as yet, know them, is beside the question; improved knowledge may reveal them. In this case, absolute motion could be determined. Why should not the outermost boundaries of the finite universe act as an absolute frame of reference? We cannot determine them at present, but they certainly are there and may possibly be discovered in the future. The existence of a diurnal

variation of cosmic rays reaching our earth, which now seems established, might possibly become, as some scientists believe, a method of determining the position and motion of the earth with regard to some fixed medium or point of reference in space. If this be true, the basic assumptions of relativity will have lost much, if not all, of their validity.⁸

Besides, if the equivalence of the reference-systems is stressed, it should be equally true to say that the sun and the stars revolve around the earth as it is to say that the earth and the planets revolve around the sun; as a matter of fact, from the standpoint of the terrestrial observer, they do appear to revolve around the earth once in every 24 hours. This, however, cannot consistently be maintained. The *rotation of the earth* must be upheld, because only on that supposition can science explain the tides, the bulging at the equator and the flattening at the poles, the deviation of the pendulum and of the gyroscope, and similar phenomena. To assume the contrary, would involve science in insurmountable difficulties. It is inconceivable that the enormous masses of the stars galaxies, thousands and millions of light-years distant, *could revolve around the earth in the period of a day*. The universe would burst asunder. It is a principle of the Theory of Relativity that bodies would have an infinite mass, if they attained the speed of light. Considering the distance to be covered by the universe at large, if it revolved around the earth, the stars would travel at a rate far in excess of the speed of light; and that, the Theory of Relativity itself states, is an impossibility. Theoretically, in the case of two isolated

reference-systems, motion may be considered relative, so that neither system has a preference; practically, however, in the case of the actual physical conditions of the earth and the stars, the earth has a preferential position as a reference-system, and its rotational motion on its axis should be considered *absolute*, not merely relative. Of course, the Restricted Theory of Relativity applies, not to the accelerated motion of a rotational system, but to the rectilinear motion of an inertial system. It must be remembered, however, that it is a cardinal principle of the theory that absolute motion is meaningless and that all motion is relative. It was the express purpose of the General Theory of Relativity to extend the principle of relativity to accelerated motion, including rotational movement, so that all reference-bodies (K , K' , etc.) are equivalent for the description of natural processes, *irrespective of the character of their motion*. Under this supposition, it would, according to the principles of relativity, seem impossible to attribute an absolute character to the rotation of the earth. Reason, however, demands that this rotational motion be considered absolute.

Then there is the Fitzgerald-Lorentz *contraction* of moving bodies in the direction of their motion. This looks very much like an hypothesis made expressly for the purpose of eliminating an inconvenient phenomenon. If all bodies, even clocks and measuring rods, contract in this manner, so that no absolute standards of measurement remain, such a contraction and its amount could never be detected experimentally. The hypothesis seems to be nothing more than a pure assumption. Concerning this

contraction, Eddington remarks: "It may seem somewhat strange that we should be able to deduce the contraction of a material rod and the retardation of a material clock from the general geometry of space and time. But it must be remembered that the contraction and retardation do not imply any absolute change in the rod and the clock. The 'configuration of events' constituting the four-dimensional structure which we call the rod is unaltered; all that happens is that the observer's space and time partitions cross it in a different direction."⁹ This explanation is hardly convincing. It makes the contraction a matter of mere appearance, not a reality. An observer on the earth would not be able to observe it, but an observer, let us say, on Mars would. How do we know? Since we have no means of verifying the contention, the theory is a mere assumption. Again, if the contraction is not real, how could the mechanical apparatus be affected by it, so that the experiments were more or less negatived in their general results?

These are a few of the problems and perplexities — there are more — which confront the Theory of Relativity, when viewed from the standpoint of science.

PHILOSOPHIC OBSERVATIONS

Viewed from the standpoint of philosophy, we encounter further difficulties in the theory. If the Theory of Relativity were purely scientific, philosophy would not be called upon to pass judgment on it. The theory, however, contains certain implications of a philosophic character which cannot

go unnoticed; they amount to a metaphysics of nature, and that is a distinctly philosophical problem.

A persistent confusion of the conceptual and real order seems to underlie the thinking of most relativists. The theory had its origin in the difficulty of making scientifically exact measurements of motion, space (dimensions), and time. Relativity sought more accurate mathematical methods for the description of physical events and laws. It seemed more reasonable to express relations and measurements of things in motion, space, and time by means of frames of reference rather than to attempt to express them in absolute terms. Scientifically, this is admissible. Most relativists, however, then took the fatal step of ascribing to the objects themselves what pertained only to their modes of measurement; the relative measurement of motion, space, and time was transferred to these entities themselves so that they themselves lost absolute meaning. It is true, of course, that motion, space, and time do not exist as absolute entities, distinct from, and independent of, the bodies in which they are present. In this sense, it is true to say that they are 'relative' in character. If, then, relativists intend nothing more than the assertion that we cannot make an absolute determination of the *quantitative measurement* of these realities, unless we know the relation of our frame of reference to other frames, the assertion need not be impugned. But when the assertion is made that motion, space, and time have no 'absolute significance' *in themselves* as realities in nature and that they cannot be recognized as such, then the assertion is a philosophical error.

Motion, space, and time, in the sense of real motion, space, and time, have an absolute significance and can be recognized as such. I cannot doubt the testimony of my consciousness that I actually move in space and time, when I walk along the street or when I drive an automobile along the highway, and that it is not the buildings and countryside which move while I am at rest. *Theoretically* and *abstractly*, merely as a mathematical equation and construction, it may make no difference whether I state that I or the objects around me are moving or at rest; the result of the calculation would be the same. *Practically* and *concretely*, however, I experience no difficulty in determining that I am really moving in an 'absolute sense,' even though I may not be able to determine the rate of this motion with reference to some problematical 'fixed points' somewhere out in interstellar space. Einstein maintains that it is impossible to ascertain which of two frames of reference is in motion and which at rest; the quality of the motion is the same, whether, for example, the train or the earth moves. He is wrong. If four trains move out of a station and each goes in a different direction — north, east, south, and west — their motion is real and has absolute significance; otherwise one must assert that the earth moves in opposite directions at the same time. The same applies to 'space' (dimensions) and 'time.' To say that 'time' itself can be reversed simply because light consumes time to signalize the existence of a cosmic event far out in the universe, would undermine the foundation of all science, the *Principle of Causality*; because under such a supposition an effect could have existence prior in time to the causal action which gives it existence.

Relativists frequently speak of 'motion,' 'space,' and 'time,' as if they were the product of the observer's mental processes and not realities in nature. That is a remnant of *kantism*. The correct philosophical notion of these realities has been elucidated in previous chapters and need not be repeated here.

Relativists generally discard the idea of an aether, because it cannot be observed and measured. On the same grounds they should discard energy as a factor in the universe. No one observes energy as such, but only the transformations effected by energy. Furthermore, in the place of aether they substitute *space-time*. They speak of 'space-time' as if it were an entity existing independent of the bodies which make up the world; to all appearances, this 'space-time' performs all the functions of the discarded aether. That the absence of a real aether involves the doctrine of an *action at a distance*, does not worry them. Notwithstanding the fact that relativists reject Newton's idea of 'absolute space' and 'absolute time,' this four-dimensional space-time bears a strong resemblance to both. The description of the universe as a 'non-euclidean *space-time continuum*' with a 'curvature' which leads back to its starting point, so that there might be 'phantom' suns and stars in the heavens, is something so weird that one cannot avoid the suspicion that a mathematical formula and a geometrical construction has been substituted for the reality of the physical world. So far as our actual experience of the world and its dimensions are concerned, it is *euclidean* in every respect. To deny the essential validity of

this experience, is tantamount to a destruction of the foundation of all knowledge.

There is much in the Theory of Relativity which is constructive and sound. But there seems to be something radically wrong with its premises, when they lead to conclusions so far removed from the concepts of conservative science and philosophy.

SUMMARY OF CHAPTER XVIII

The Theory of Relativity, though mainly a theory of physics, involves *metaphysical* concepts.

1. *Origin of the Theory.* It has its origin in the *problem of motion*. Can we find an 'absolute frame of reference' which would give us absolute standards of measurement? Scientists sought it in the *aether*. The experiments of Michelson, Morley, Miller, and others, failed to find an 'aether-drift' of the amount expected. Fitzgerald and Lorentz explained this by the 'contraction' of bodies in the line of motion.

2. *Special Theory of Relativity.* Einstein, in 1905, formulated this theory as an explanation of the uniform rectilinear motion of inertial systems. When we have two co-ordinate systems, K and K' , both of which are moving uniformly in a straight line with respect to each other, then any mass which has a uniform translatory motion relative to K will also have a uniform translatory motion relative to a second co-ordinate system K' . There is a relativity of 'time' and 'space.' Light is constant in its velocity, irrespective of the velocity of motion of the radiant body. Every inertial system can consider its own space and time to be the true space and time, because 'space' and 'time' have no absolute significance; they depend on the observer.

The Special, or Restricted, Theory is based on *two postulates*:

1. When two systems move with a uniform linear velocity relative to each other, observers in either system, by observation and measurement of phenomena in the other, cannot learn anything more about the motion than the fact that there is this relative motion;
2. Measurements of the velocity of light in either system will always give the same numerical value, no matter what the position of the source of light happens to be; in a vacuum the speed of light is constant.

3. *General Theory of Relativity*. Einstein, in 1915, expanded the theory to include *accelerated* motion. The general principle reads: All reference-bodies (K , K' , etc.) are equivalent for the formulation of the general laws of nature, or description of natural processes, *irrespective of the character of their motion*. More abstractly: All gaussian co-ordinate systems are essentially equivalent for the formulation of the general laws of nature.

Einstein combined the concepts of inertia and gravitation and enunciated the *Principle of Equivalence*: For any one particle in a gravitational field it is possible to replace the effect of the field by a mathematical transformation of axes; gravitational mass and inertial mass are equivalent.

4. *The Non-Euclidean Universe*. The real three-dimensional world is obsolete and must be replaced by the *four-dimensional space-time with non-euclidean properties*. The world is cylindrical-curved in the three space

dimensions and straight in time dimensions. The curvature of space-time is such, that the rays of light can return to their starting point.

5. *Scientific Observations.* The theory seems to rest upon an *insecure foundation*. The Michelson-Morley experiments were not altogether negative, but positive, in their detection and measurement of an aether-drift. The *postulates* are not self-evident. It has not been proven that light is constant under all conditions. Nor is it clear that all reference-systems are equivalent and that absolute motion is meaningless. The rotation of the earth should be considered 'absolute,' otherwise we could assert that the universe rotates around the earth in 24 hours. The Fitzgerald-Lorentz contraction is an assumption made without positive proof.

6. *Philosophic Observations.* The relativity metaphysics of nature seems to rest to a large extent on a *confusion of the conceptual and real order*. Relativists ascribe to the objects themselves what pertains only to their modes of measurement. 'Motion,' 'space,' and 'time' have an *absolute* significance and can be recognized as such; experience proves this. If 'time' could be reversed, the Principle of Causality would be undermined.

Space-time becomes a real entity and is substituted for the aether. It involves 'action at a distance.' The 'non-euclidean space-time continuum' appears to be a mathematical formula and a geometrical construction substituted for the reality of the physical world. Our experience shows that the world is *euclidean*.

Chapter 19

BEGINNING AND END

ONE OF THE MOST FASCINATING COSMOLOGICAL PROBLEMS IS that of the beginning and the end of the world. Even the illiterate person, looking into the skies on a clear night, cannot but wonder whence the stars came and whither they go, whether they were there always and whether they will remain there forever. The problem of the origin and the final destiny of the world occupied the minds of the earliest thinkers. It is a burning question among the scientists and philosophers of our own day, because the materialistic trend of the times has added a new interest to the age-old search for the answer. It was inevitable that the increased scientific knowledge of the universe would furnish data which might be of assistance in attempting a solution.

SCIENTIFIC COSMOGONY

There is no doubt in the minds of scientists and philosophers alike, that the *earth* arrived at its present state through some process of *natural evolution*. Geology and paleontology have uncovered an overwhelming amount of evidence which convinces the impartial student that a

geogony, or evolution of the earth through natural agencies, actually took place. As was pointed out before (Chap. 15), this evolutionary process consumed hundreds of millions, and most likely billions, of years. It was but natural to inquire whether the solar system and the universe at large, as we know them now, were not the result of an evolution of some kind. Such a theory of the origin and development of the universe through natural causality is termed *cosmogony*. Leaving aside the cosmogonical ideas of the older scientists and philosophers, who had no accurate knowledge of the universe, we will restrict ourselves to the theories based on scientific data.

First among these is the *Kant-Laplace Nebular Hypothesis*. This hypothesis attempted to explain the origin of the solar system. *Kant*, in 1755, proposed the theory that the material which gave rise to the solar system was a tenuous gas. It covered the area of the present system in a uniform manner. The heavy elements attracted the lighter ones. Repelling forces were also at work, giving a rotary motion to the nuclei of this material. There were many such nuclei; but frequent collisions gradually formed definite centers of condensed material, so that eventually the entire material became concentrated in the massive central sun and the planets, with minor satellites and asteroids. In this manner he sought to explain why the planets and the smaller bodies are all in a plane and move in the same direction in nearly circular orbits.

Laplace, in 1796, proposed a theory which resembled Kant's in its fundamental assumptions. The sun, he assumed, was shrouded in the beginning with an

atmosphere or nebula of hot, slowly rotating, gaseous material. Upon cooling, this atmosphere contracted and acquired a faster rotation, until all the material had arranged itself in the plane of the sun's equator. Eventually this rotation increased to such a degree, that the centrifugal force of the equatorial nebular mass surpassed the attraction of the sun, and then this mass spun out into space. Left alone to itself, the disconnected nebula condensed toward the center, forming the nucleus of a planet, which in turn was enveloped with a nebula of gaseous material. Paralleling the process of the sun, satellites were then formed out of the material surrounding the planet, until the remaining material was used up. In the meantime, the sun went through a similar process, repeating the performance until all the known planets, together with their satellites, came into being. By an extension of the solar theory to other star systems, the development of the universe could be explained. The Nebular Hypothesis is now abandoned. The mechanics involved violate the law of the conservation of moment of momentum; the gaseous material would in all probability be dissipated into space and not concentrate into solid bodies; the theory does not account for the eccentric orbits of comets and asteroids, for the east-to-west motion of some satellites, and for the fact that the inner moon of Mars revolves in a period shorter than the planet's own period of rotation.

The *Planetesimal Hypothesis* was advanced by *Chamberlin and Moulton* at the beginning of the present century. According to this view, a very large number of

diminutive planets, or 'planetesimals,' revolved around the sun; they were more or less in the same plane and traveled in intersecting orbits. The configuration in general was that of a spiral nebula with centers of condensation. Gradually, in the course of the revolutions, *collisions* occurred between these centers and the planetesimals; the result was the growth of the planets and their satellites by continuous accretion. Due to the fact that fewer collisions occurred in some regions, the smaller planets and the asteroids retained orbits of greater eccentricity and inclination. In order to account for the original 'spiral' structure, it was suggested that the passage of some large star might have occasioned great *tides* in the sun; in consequence of these tides, enormous masses of gas were torn out of the sun in opposite directions, i.e., toward and away from the star. After the star had passed, portions of this material were drawn back into the sun, increasing its rate of rotation; other portions formed the planetesimals. *Jeans* and *Jeffery* modified this theory to some extent. They assume that the separated masses became *liquified* through cooling. These large liquified masses eventually became the planets and their satellites. This tidal action of the passing star would account for the general plane and the west-to-east direction of the whole system, because these ejected masses followed the direction of the orbit of the star. *Russell* objected to this tidal theory on the grounds that the average relative angular momenta of the different planets are far in excess of what the theory can allow. To offset this, he assumes that the sun was originally a *double star*; one of the two stars exploded under the influence of

the passing star, and a portion of its material became the planets.

These hypotheses are ingenious. The initial conditions, however, are *arbitrarily assumed*. There is, for example, no real evidence of any kind to show that a star ever passed so close to the sun as to cause tidal eruptions of a nature which could give rise to the planetary system. These hypotheses are interesting conjectures of what might plausibly have happened. None of the cosmogonical theories advanced so far offers any suggestions as to what the primordial stuff of the universe was like, how it originated, and in what manner it developed into the present world system. We can safely assume that an actual evolution of some kind took place in the course of the eons of time. The fragmentary character of meteors, the various stages of incandescence among the stars, the flaming eruptions of 'novae' ('new stars') in the heavens, the presence of vast nebular patches in interstellar space, the constant expenditure of enormous quantities of energy — all are evidence of causal agencies at work which must have produced far-reaching changes in the development of the universe. As yet, however, science has not been able to piece together the evidence and give us a comprehensive picture of the evolution which probably took place.

CONTINGENCY OF THE WORLD

Science, then, is of little help to the philosopher in his endeavor to solve the problem of the beginning of the world. It offers no factual evidence concerning the

development of the universe in the remote ages of the past; much less is it able to state whether the universe had a beginning in time or whether it was present from all eternity. The philosopher, studying the nature of the bodies comprising the universe, must arrive at a decision, if he can, by applying the *principles of reason* to the data of science. The first step in this direction will be taken, if he can answer the question: Is the world and its contents 'necessary' or 'contingent'?

A being is said to be necessary, when its nature or essence is such that it *demand*s existence. It is *contingent*, when its nature or essence is such that it does *not demand* existence. The necessary being cannot be nonexistent; it must exist. The 'contingent' being can be nonexistent; it need not exist. It would be a contradiction in terms, if the 'necessary' being did not exist; but it would involve no contradiction, if the 'contingent' being did not exist. In the 'necessary' being existence is included in its very essence; in the 'contingent' being existence is superadded to the essence.

The world is contingent.

It is clear, for one thing, that organic life and the organisms themselves, taken singly and collectively, are contingent beings. The single organisms, whether plants, animals, or men, come into existence and pass out of existence. Organic life in general did not always exist on our globe; it began at a definite period in geological history. How it originated, is beside the question. In its earlier stages of development, the earth was a superheated mass, and no organism could live under such conditions. Similar

conditions still prevail on many of the stars, and life, as we know it, is impossible there. 'Whatever planets and stars there may be which could now support life, they could not have done so in the past, because they, like the earth, must also have been in a superheated condition, incapable of sustaining life. Organisms, therefore, are certainly contingent and not necessary in their being and existence.

Inorganic beings are also contingent. There is nothing in the single *stars* and other celestial bodies to show that they are necessary beings. On the contrary, everything points to the fact that they originated through a process of cosmic development. They undergo continual change. Some even break up and lose their identity; the existence of meteors is a clear indication that they are the fragments of disrupted stars. This proves that stars, as stars, are not necessary beings. And what is true of one star, must be true of all, because they all consist of the same materials and are structurally alike. Besides, it involves no contradiction to assert that, if *any* single celestial body ceased to exist, the universe would still be there. More stars could exist than actually exist, and fewer stars could exist than actually exist. The *number*, *size*, and *duration* of the stars and of all bodies in the universe could be different; there is nothing necessary in all this, as if a change in the configuration of the universe would be impossible. In fact, it is conceivable that an entirely different kind of world could exist in the place of the present one; there is nothing contradictory in such an idea. Hence, the universe, as now constituted, is not necessary, but contingent.

The entire universe consists of the same types of *chemical compounds* and elements. It is a known fact, however, that chemical compounds are continually made and unmade. They have no necessary existence. They come and go in a ceaseless process of change. Old compounds lose their identity and new compounds take their place. Even the elements are contingent in their being and existence. This is seen most clearly in the case of the radioactive elements; they suffer a spontaneous disintegration. All elements can be changed by artificial bombardment in the laboratory. They also change to a great extent through chemical reaction and ionization. It follows, then, that chemical compounds and elements are contingent beings.

Even the *subatomic particles* cannot be said to be necessary, in the sense that their nonexistence would involve a contradiction in terms. We know that the number of electrons exceeds by far the number of protons, neutrons, positrons, etc.; the number of the latter, therefore, could be larger than it is. Similarly, why should it be inconceivable that these particles be increased or decreased, *absolutely speaking*, in number, volume, mass, electric charge, and so forth? Modern scientists are insistent that mass and even matter can be converted into energy, and reversely. If this were true, it would be an incontrovertible proof that matter and energy are contingent in their being and existence. We do not agree with this, at least in so far as the 'ontological mass' is concerned, because it seems impossible that matter, which is a substance, can be changed into energy, which is a

qualitative accident. Be this as it may, no one can prove that these particles are individually so necessary in their being and existence, that their nonexistence would be *intrinsically impossible*; it is only on this supposition that they can be said to be 'necessary.' Since everything else in the universe is contingent, they also must be considered 'contingent.' At any rate, the burden of the proof rests on the shoulders of the opposition. The very fact that all material beings are influenced by others and have a natural *relation* to others (for example, electrons and protons, due to opposite electric charge), is indication enough that they are *essentially relative* in their being; this excludes any sort of essential independence and necessity in the individual.

BEGINNING IN TIME

Everything in the universe is contingent; no being is such that we would be compelled to consider its nonexistence as intrinsically impossible. We must conclude, therefore, that the existence of all bodies is not a part of their essence, but is something adventitious. This brings up the question: Does the universe exist *from eternity*, or did it, as a matter of fact, have a *beginning in time*?

In speaking of 'time' in this connection, it will be well to recall that the notion of 'time' is derived from a measurement of the motion of bodies. 'Time,' as such, is a conceptual entity, with its foundation in the changes occurring in bodies. *Concrete time* is coincident with the particular duration of the particular bodies. Outside 'concrete time' there is nothing but 'possible time,' and this

is conceived by the mind as 'absolute time.' *Actual time*, therefore, has no existence except in the concrete time of particular bodies. Consequently, when the question is asked whether the universe existed from eternity or had a beginning in time, the sense is: Does the world exist *without a beginning*, or did it *have a beginning* and time have a beginning with it? If the world exists without a beginning, then it exists from eternity, and time also exists in it and with it from eternity. And since the universe is not an abstraction, but consists of actual bodies and material entities, it is a question here about the absolute beginning of the materials out of which the universe evolved in the course of the ages.

The universe had a beginning.

This follows logically from the *contingency* of the world. Since none of the beings in the world are such in their nature or essence that existence must be considered as necessary to them, so that their nonexistence is inconceivable and impossible, there must be a *sufficient reason why they exist rather than not exist*. Nothing can happen without a sufficient reason to account for it happening.¹ Since existence is not essential to a contingent being, the sufficient reason for its existence does not lie in the essence of this being itself. It follows, then, that a contingent being must have the sufficient reason for its existence in some other being which is *prior* to it and *gave* it existence. If this were not so, the contingent being would have no sufficient reason for its existence, and it would never have existence. This means, that its existence is a given and *caused* existence, and it did not always have

existence, but was brought from nonexistence to existence by an extraneous cause. This means further that its existence had a beginning, and concrete time had a beginning with it. Hence, the universe, which is contingent, had a *beginning in time* and does not exist from eternity

Other considerations lead to the same conclusion. Science has been unable to find any formless, homogeneous primordial stuff, out of which the universe might have evolved as out of some ultimate material. The universe is composed of bodies, compounds, elements, and subatomic particles; the latter are, so far as science knows, the ultimate actual components of all things. Now, there must be a sufficient reason to explain the peculiarities of these particles: their *kinds*, their *size*, *weight*, *mass*, *number*, *energy content*, *electric charge* or absence of charge (i.e., with respect to neutrons, if they are without charge), mutual relationship, and distribution throughout the world. The reason for these peculiarities does not lie in these particles themselves. Each particle is a unit for itself and could not have had any influence on the conditions of other particles, especially when they are millions of miles apart. Nevertheless, there must be a sufficient reason for the arrangement of all this; it cannot be accidental, because accident and chance have no regulating influence. Hence, the sufficient reason must lie in some other being.

Similarly, all beings in the universe are governed by physical *forces* which act according to the norms of *physical laws*. These forces are active throughout the universe, fashioning all bodies and directing their development. Gravitation, for instance, controls all beings, from electrons

to stars; nothing can escape its power. Subatomic particles have an inherent tendency to enter into the formation of different kinds of elemental atoms; atoms have an inherent tendency to combine into definite compounds; the compounds are forced to unite into large aggregates, such as asteroids, moons, planets, and stars. Yet, each particle and atom is a unitary entity in its own right. To say that they exist from eternity and never had a beginning in their existence is no rational explanation for these phenomena of nature, because 'eternity' is a mere matter of 'duration.' It would still be necessary to find a sufficient reason for these facts. This sufficient reason cannot be found in these bodies themselves, because they, singly and collectively, are *subject to the laws of nature as a whole*. The single particles and atoms cannot explain the forces and laws which dominate the universe in its *totality*. Being completely subjected to laws, these laws must have been imposed on them, because the laws themselves express a rationality and intelligence which these inanimate bodies do not possess. It is obvious, however, that these forces flow out of the essence of the beings, since they result in the natural actions of these beings. The only sufficient reason which can account for the essences, forces, and laws present in the universe, is this: an extraneous cause *produced* them in such a manner that all work together harmoniously to form a cosmos. This explanation alone is in accordance with reason.

Finally, *matter*, which is the fundamental principle and base common to all things in the world, cannot be eternal. It is essentially *inert*, and as such it is *indifferent* to rest or

motion. Given existence, however, it must be either at rest or in motion. Hence, if it exists of itself and has the sufficient reason for its existence in itself, it could not be indifferent to rest or motion; its eternal nature would of necessity be such that it would be either at rest or in motion. Consequently, if it were originally at rest, it could never go over into motion; and if it were originally in motion, it could never come to rest. No change in this original condition would ever be possible, because it would be an *eternal* condition. As a matter of fact, however, bodies are indifferent to rest or motion, and changes from rest to motion and from motion to rest are characteristic of all bodies; *inertia* is a common property of bodies, and inertia implies an indifference toward both rest and motion. Hence, matter cannot have existed from eternity; it must have had a beginning.

The universe, then, had a beginning. This brings us to the final question: What or who gave it existence so that it had a beginning?

CREATION

By creation we understand an act whereby the entire substance of a being is brought *from nonexistence to existence* (*productia totius substantiae ex nihilo sui et subjecti*). When a new being originates, for example, a chemical compound, a plant, an animal, or a human being, this specific entity had no previous existence and then becomes existent. Before production it was, as such an entity, actually nothing; after production it is an actual

entity in the order of real beings. Such a production is said to be *ex nihilo sui*. This is not creation, because the material elements, which compose it, were already in existence. In order that such a production be termed 'creation,' it is necessary that this specific entity be produced outright, without a pre-existent 'subject' or material of any kind contributing toward the production of the entity. This is a production *ex nihilo subjecti*. The *total substance* must be produced, so that it passes from nonexistence to existence with respect to everything that it is and has, no pre-existent material being used in its formation.

Since the entire universe is contingent and had a beginning, it is obvious that, previous to this beginning, it had no existence. This also includes the *matter* out of which all beings in the universe are made. Hence, not only the specific entities in the universe, but also the 'subject' or 'material (matter)' itself, passed from nonexistence to existence. This passage from nonexistence to existence demands a sufficient reason. The universe is not an emanation or determination of the Absolute or of God; this possibility was eliminated when it was proved that pantheism is irrational and false. Hence, the sufficient reason for the existence of the universe can only be found either *in the universe itself or in an extramundane cause*.

The sufficient reason for the existence of the universe is *not in the universe itself*. If it were, it would have had to bring itself from nonexistence to existence; that is equivalent to the assertion that it was the cause of its own production. Such an assertion, however, involves a contradiction in its very notion. It was as yet nonexistent,

because it had to give itself existence. Yet it must also have been existent, because, to be the cause of its own existence, it had to be the active agent of its own production, and a being must exist in order to be active. Under the supposition, therefore, it would be both nonexistent and existent in the same set of conditions. That is a contradiction and intrinsically impossible.

The cause, then, which gave existence to the universe, must be one which is *outside* the universe itself and is *prior* to it. It must be 'outside' the universe, in the sense that it is not a part of it or identified with it. If it were a part of the universe or identified with it, it would partake of the contingency of the universe and thereby also require another cause. It must be 'prior' to the universe, because every cause is prior to the effect it produces. Hence, the cause which brought the universe from nonexistence to existence is an *extramundane cause*. And since the 'total substance' of the universe is the term of the causal act of production, this production is *creation* and the cause is a creating cause or creator.

THE CREATOR

It is always a logical procedure to argue from the perfection of the effect to the perfection of the cause. The cause may have a greater and higher perfection than the effect it produces, but it can never have less. No one can give what one does not possess, but one can give less than one possesses. Hence, any perfection which the effect manifests must be found to at least an equal degree in its producing

cause. From these simple principles we are able to deduce a number of truths concerning the creating cause of the universe.

This creating cause must be an *intelligent person*. Man is an integral part of the universe, and he is an intelligent person. It makes no difference whether we assume that he is the product of a direct creation or the result of evolution. Man is far superior to animals, brutes, and inanimate things, because of the fact that he is an intelligent person. If he is the product of a direct creation, the creating cause cannot be less, but must also be an intelligent person. And if he is the result of an evolutionary process, the developmental factors of this process must ultimately be referred to the creating cause of the universe as their ultimate source. Hence, the creating cause is an intelligent person. We call Him the *Creator* or *God*.

God is very great in His *power*. A glance at the magnitude and multitude of the stars is all that is required in order to bring home to our mind the greatness of His power. No word picture can adequately describe a power which has built a world that reaches out through distances which can be measured only in terms of light-years and parsecs. The tremendous energies at work, whether in the heart of an atom or in the gigantic furnaces of the innumerable suns, baffle our imagination. More than anything else, however, the absolute power involved in the creative act, producing the vast expanse of the wheeling galaxies and capable of producing more universes in limitless numbers and diversifications, out of sheer nothingness, postulates an inconceivable perfection.

God is very great in His *knowledge* and *wisdom*. Everything, from the dervish dance of the electrons to the majestic parade of the constellations, is arranged according to number and measure, balance and symmetry, rule and law, so that the order of nature is indeed a thing of beauty. Each discovery of science reveals new marvels and discloses new mysteries. The formulation of the laws of nature tax the capabilities of the mathematical geniuses of mankind to the utmost. Man, despite his ingenuity, has succeeded but in a very small degree in tracing the intricate pattern of the world's design, so deep and hidden are the workings of nature in its simplest and most commonplace operations. From beginning to end this world is a teleological world, with a disposition of means toward ends which is precise in its minute details and vast in its cosmic proportions, so that the eye of a gnat and the glow of the sun fulfill a divine purpose of mutual relationship.

The universe is indeed a mirror for the perfections of the Creator. The discussion is restricted to these few considerations, because these perfections are so clearly manifested in physical nature. A different department of philosophy, theodicy, gives a full treatment of God and His attributes.

The question has been asked: Can God *create* something so that it could *exist from eternity*? In that case, the being would have a beginning; however, since it was created in eternity, it would have existed from all eternity. Some scholastics, among them St. Thomas,² maintain that the impossibility of an 'eternal creation' cannot be clearly demonstrated. They base their contention on the grounds

that, since God is eternal and has the power of creation, He can exercise this power in eternity; hence, an eternal creation should be possible. Most scholastics, however, claim that an 'eternal creation' involves a *contradiction*. The difficulty lies, not with God, but with the *creature*. An eternal creature, they say, is like 'wooden iron,' a square circle,' and a 'stick with one end extending infinitely.' Let us suppose that such a creature existed now. It exists in time, and time consists of a *succession of moments*, and this number of moments increases daily. But it would take an infinite number of moments to fill out the duration of God's eternity, and an infinite number is incapable of increase. A year ago the number of moments of this eternal creature's duration was smaller than it is today, and a year from now this number will be larger than it is today, and so forth, as time rolls on. How can this number be infinite in the past, if it grows continuously with the years? A smaller number certainly is limited. But if it is a limited number, it is finite and can be exhausted through subtraction or division. Infinity of duration in the eternal past, however, cannot be exhausted, or we will reach a moment which is the first, beyond which this creature did not exist; and in that case it is not 'eternal' but 'in time.' Hence, it seems clear that an 'eternal creature' is an idea which implies an *infinite finite duration*. It is 'infinite,' because the supposition is that it is 'eternal'; it is 'finite,' because successive duration brings on a constant increase in the number of moments, which leaves the present number always limited. This is a case of the confusion of *indefinite and infinite* number. The argument does not apply, of course, to God's eternal

existence, because in His duration there is no succession of moments, but a complete and simultaneous possession of interminable life.

God alone is eternal. Creatures are temporal. No finite being can have an existence which reaches back through eternity. The world, as was shown, is limited and contingent; it, too, must have had a beginning in time. Having had a beginning in time, it must have been brought from nonexistence to existence through God's act of creation. God existed prior to the world. He is not only extramundane but supra-mundane, incalculably superior to the world in perfection of being and of existence. It is natural, however, that the world should reflect to some extent the perfections of its Creator, because the perfection of an effect must be included, in some manner, in the cause which produces it.

THE END OF THE WORLD

Will the universe come to an end? Or will it last forever? While science can tell us very little about the original development of the cosmos, its data enable us to forecast the final destiny of the universe with a fair amount of accuracy.

The present world will come to an end.

This end is inevitable, because of a peculiar condition which attaches to the energy working in the universe. Energy is the capacity to do work, and it is of two kinds, kinetic and potential. According to the law of the Conservation of Energy, energy may be changed in form

from one kind to another, but the sum total of energy in any closed system is always the same quantity. Kinetic energy can change into potential, and potential energy into kinetic; but the sum of both is always constant. As the one increases, the other decreases in proportion, and reversely. The universe being a 'closed system' the total amount of energy in all forms, present in the universe, never changes; energy is merely transformed, but no energy is ever really gained or lost. This is what is meant by the physicists' statement that 'energy can neither be created nor destroyed.'

All the activities of natural bodies are the result of energy. Due to the fact that one form of energy can be transformed into another, while the sum of all energy is constant, the conclusion might suggest itself, that a complete 'cycle' of energy transformation should occur, so that the universe, similar to a perpetual-motion machine, would go on forever. This would indeed be the case, if all processes of nature were reversible with an absolute degree of efficiency. However, *natural processes are actually irreversible*. This is due to the peculiar character of the energy of heat.

All natural processes are accompanied to some extent by heat. Heat has a tendency to *diffuse* itself into surrounding objects and, because of this, becomes scattered, so that a completely reversible process is impossible. The reason for this lies in the *Second Law of Thermodynamics*, which states that heat cannot pass directly from a cold to a hot body of its own accord. In order that heat be able to do work, there must be a difference of temperature between

two bodies. Work is done, when heat passes from a body of higher temperature to a body of lower temperature. Once the temperature of the two bodies is equalized, *heat can do no work*. Only when another body of lower temperature is contacted, can this heat do work again. This process will continue until heat has reached the *lowest temperature level* existing in the universe. On this level no more work can be done, so that heat at this stage becomes *potential* energy which *can never become kinetic again*. This is a necessary consequence of the Second Law of Thermodynamics.

Only if some *other form of energy* were to reverse the process by transforming this heat into mechanical energy, electrical energy, chemical energy, and so on, could this heat energy on the lowest temperature level again become kinetic. This, however, is not possible, at least not forever. The reason is simple. For one thing, one of the most important *sources* of energy in the universe is heat. This is plainly noticeable in the sun and stars. Secondly, in all processes of nature a certain amount of energy is always transformed into heat, through friction, chemical action, etc. Now, much of this heat is lost for a reversible process by conduction and radiation into space. Witness the sun and the radiant stars. The chemical processes taking place in these storehouses of energy develop enormous quantities of heat, most of which is radiated into the extremely cold regions of interstellar space. This heat can never be recaptured and turned back into the sun and stars, because heat cannot pass from a cold to a hot body of its own accord. It will keep on doing work until it reaches the

lowest level of temperature out in space; having brought about an equilibrium of temperature there, it is now *unavailable for work*. Little by little, degree by degree, even though it takes billions times billions of years, the energy sources in the universe will become depleted, because their finite energy has gradually turned into heat and radiated away. In other words, a *constant degeneration of energy* is taking place in nature. The amount of energy available for work is constantly being converted into energy unavailable for work. The time must inevitably come when *all forms* of energy have changed into *dissipated heat* in a state of *cosmic equilibrium of temperature*. When we consider the immeasurable expanse of the interstellar space of the universe, compared to the sources of energy in the stars, it is safe to assume that the equalized temperature of the universe as a whole, after all available sources of energy have been changed into diffused heat, will not be far over Absolute Zero.

In formulating the ratio between the available and unavailable energy of a thermodynamic system, scientists speak of *entropy*. 'Entropy' is defined as the mathematical factor which is a measure of the unavailable energy in a thermodynamic system. It measures thermodynamic degeneration. Broadly speaking, entropy gives us that amount of the heat content of a closed system which can no longer be converted into kinetic energy and is, as such, unavailable for work. In consequence of the degeneration of all forms of energy into diffused heat, there is a *constant increase of entropy* in all natural processes through the universe. The sum total of all kinetic and potential energy is

still the same and constant, but the amount of energy available for work is growing less and less as time goes on. This fact is expressed by science in the *Law of Entropy: The entropy of the world tends toward a maximum, while the ectropy (free energy) tends toward a minimum*. Eventually, therefore, all kinetic energy of the universe will be converted into potential energy, the potential energy of heat in a state of equilibrium on the lowest level of temperature, where nothing can ever bring it back to a state of kinetic energy, because in the closed system of the universe there is no available energy left to introduce a reversible process. It would take energy from another universe to reverse the process; but that is impossible, because such a universe can have no contact with ours, since both are independent 'closed systems.'

The universe, as presently constituted, must die an entropic death. Due to friction with cosmic dust, to collisions with meteors, to the tidal action of their masses, the revolution and rotation of planets, solar systems, and star clusters will slow down, and gravitational attraction will force all celestial bodies to spiral toward each other. There should be a gradual *collision* of all bodies in each system, until the system collapses to form an enormous central body. The same end should occur with all systems relative to one another. This will, of course, liberate great quantities of energy for a period of time; but the heat generated in such collisions will also be radiated into space. The catastrophic end-result cannot thereby be averted.

Some scientists are convinced that *atoms are being rebuilt* somewhere in the vast reaches of space. This view is

probably nothing more than wishful thinking, coming from the desire of maintaining a world which is eternal in its duration and processes. There is nothing inherently impossible in the hypothesis. We must bear in mind, however, that there is *no concrete evidence* to support such a hypothesis. These scientists relinquish the solid ground of scientific data for the airy tenuity of arbitrary assumptions, because they postulate the rebuilding of the universe as the result of *physical agencies*, and such agencies, so far as science knows, are not available.

The processes of the world, therefore, do not form a reversible cycle which, like a revolving wheel, always returns to its starting point and keeps on forever. Rather, the world is more like a *cosmic clock*, with its spring wound up to highest tension by the hand of God from the beginning; with every process, as with every swing of the pendulum, some of the potential energy of the spring is released and changed to kinetic energy, until at last all tension is gone and the cosmic clock stops. Then the universe will be a frozen mass in frozen space, devoid of life and light and motion.

ANNIHILATION

Will the universe then be *annihilated*? Will it drop back into the complete nothingness from which the creative power of God called it forth?

Of itself, the universe will not be *annihilated*. The Law of the Conservation of Energy and of Mass preclude such a possibility. Physical agencies can change things in the

universe from one kind of body into another kind of body and can also transform one kind of energy into another kind of energy. But physical agencies can neither create nor annihilate. The universe would still remain in existence, with the same amount of matter and the same amount of energy. No activity, however, would be possible, because there would be no energy available for work. So far as the universe itself is concerned, barring all extraneous influence, it would remain forever in this *static existence* without change.

God can annihilate the world. There can be no question about the *possibility* of an annihilation of the world. God, as theodicy proves, has infinite power, because His power is identical with His being, and His being is infinite. Since all creatures, the universe included, are contingent beings, existence is not an attribute of their essence; hence, their existence is not necessary. An infinite power, however, must be capable of destroying anything which is not necessary. Hence, God can destroy, or annihilate the universe. Besides, it was God's creative power which brought the entire universe from nonexistence to existence. Just as the universe owes its first moment of existence to God's creative power, it owes every subsequent moment of existence to the same power. Were God to withdraw His power at any moment, the universe would of necessity sink back into nothingness, because the power which was capable of giving existence must by equal right be capable of taking it away. In that case, however, the total substance of the universe would cease to exist, and that is what is meant by

‘annihilation’ — a reduction of the total substance to nothing.

Will God annihilate the world? From the fact that God can annihilate the world, we cannot validly conclude that He will. Who can fathom the designs of God? St. Thomas was of the opinion that nothing created would be completely destroyed.³ Most scholastics hold a similar view. God made matter and energy *naturally indestructible*, and they conclude from this that it would not seem in harmony with the wisdom of God, if matter and energy were completely destroyed. Of course, this is no stringent argument, and these philosophers do not consider the argument to be such. The Creator may have reasons of His own, why He would grant only a limited existence to the world. On purely rational grounds, therefore, the question cannot be answered.

If God has decided to permit the universe to continue in existence forever, will it remain in the *static condition* of ‘entropic death’? This question also admits of no definite answer. It is possible that He may have made some provision in the universe itself for its rejuvenation. It is also possible that He may give to events a turn which would bring about an entirely ‘new heaven’ and a ‘new earth,’ of a kind very different from the present configuration of things. There is no limit to the possibilities, and all attempts to solve the mystery of the future, without special revelation from God Himself, is but idle speculation.

END AND BEGINNING

If the Second Law of Thermodynamics and the Law of Entropy are actually laws of nature, then the world will indeed come to an end, in so far as all activity is concerned; but the universe would continue to exist, unless God annihilated it, for all future time. This raises the important question: Would not the world, under such a supposition, exist for all *eternity*, and would this not involve an 'infinite time' with an *infinite number of successive moments*?

The answer is: The number of moments would be *indefinite*, but never infinite. Inasmuch as the number of moments in the duration of the world is at present only finite, each successive moment becomes an addition to the existing finite sum, leaving it always a *finite number*. Finite additions to a finite number, no matter how large the sum, never make an infinite number. Even if the world be not annihilated, the number of moments will always be finite, so that it can be exhausted by subtraction or division. This number will grow and grow, and never come to an end in growing, but it can never grow into infinity. Hence, if we speak of the 'eternity' of the world in the future, the word 'eternity' is not used in the strict sense as it is used of God's duration, but only in an analogical sense. The world would simply exist *indefinitely in time*. We may call this a 'potential eternity,' but it would never become an 'actual eternity.'

Reading backwards into the history of the universe, it is obvious that the *present* universe, as we know it, could not have been active from eternity, taking 'eternity' here as coterminous and co-existent with God's eternal duration. Being endowed with a limited amount of energy, every moment of activity makes a certain amount of energy

unavailable for work, due to the Law of Entropy, and such a finite amount could not possibly last through the actual eternity of God. That would postulate an *actually infinite number* of successive moments, with the necessity that an *actually finite number* of energy units could be spread out over an infinite number of successive moments, although each moment reduces the amount of available energy. That is impossible, because a contradiction in terms. If our world had been from eternity, it would now already be in a condition of entropic death, because now already the number of successive moments, having existed during the infinity of an actual eternity, would be *actually infinite*. But the world is not at a standstill. Therefore it could not have existed from eternity, but must have begun in time.

The world, then, is finite in every respect. It is finite in the number of bodies which comprise it, finite in its dimensions, finite in its energy, finite in its processes, finite in its existence in the past, and also finite in its existence in the future.

This ends our investigation into the general characteristics and basic principles of the material universe. The subject matter is vast and intricate, the problems are many and deep. Our studies took us all the way from aether to cosmos. Wherever possible, we followed in the footsteps of science, basing our conclusions on the reliable data of scientific research, so as not to lose ourselves in the quagmire of subjective speculations. Many of the operations of nature are shrouded in impenetrable darkness. In many instances, however, we feel that we have been able to give a satisfactory solution to the problems

which confronted us. We now certainly have a better and deeper understanding of the universe in which we live.

It is a wonderful world, marvelously constructed in its atomic and in its cosmic aspects. It is difficult to decide where it is more beautiful, in the extremely minute configurations of its atoms or in the dimensionally vast proportions of its stars. Both stagger the imagination and mind of man. In both aspects it is an intelligently and teleologically constructed masterpiece. Man occupies a midway position, so far as size is concerned, between the infinitesimal electron and the immense universe. He is the rational interpreter of the world, and it is logical and fitting that his position be halfway between the two extremes. Whichever way he casts his gaze, he sees the invisible hand of the Creator. Man himself is a privileged being, endowed with the intellectual capacity to recognize his and the world's Creator. He alone can give tongue to the universe, to praise the Maker of all.

SUMMARY OF CHAPTER XIX

Did the world have a beginning? And will it come to an end?

1. *Scientific Cosmogony*. Geology and paleontology show that the earth arrived at its present state through a process of natural evolution. Scientists have also attempted to develop a *cosmogony*. The *Kant-Laplace Nebular Hypothesis* postulates that the solar system originated from a nebula of gaseous material. The *Planetesimal Hypothesis* postulates that it originated from a large number of small planets through collision. The original planetesimals were the result of a passing star which occasioned great tides in the sun, drawing out enormous masses of gaseous material.

2. *Contingency of the World*. A being is 'necessary,' when its essence is such that it demands existence: it is 'contingent,' when its essence is such that it does not demand existence. *The world is contingent*. *Organisms are contingent*, because they live and die; they did not always exist. Inorganic beings are also contingent. Neither the stars, nor the chemical compounds, nor the elements, nor the subatomic particles, are such that they must always exist; their nonexistence is not inconceivable and impossible.

3. *Beginning in Time*. *The universe had a beginning* and is not from eternity. Since all things in the universe are *contingent*, there must be a *sufficient reason* for their existence; this reason cannot lie in the things themselves, or their existence would be necessary, not contingent. The ultimate components of all bodies are the *subatomic*

particles, and there must be a sufficient reason for their kinds, size, weight, mass, number, energy content, electric charge, mutual relationship, and distribution. This reason cannot lie in the particles themselves, because each particle is a unit for itself and could not have had any influence on the conditions of other particles. All are governed by physical *forces* and subject to the *laws of nature as a whole*; since they are subject to these laws, the laws must have been imposed on them by an extraneous cause which produced them. *Matter is indifferent* to rest and motion, because it is essentially inert. Such an indifference would be impossible, if matter were from eternity. Hence, all material beings are not from eternity, but must have had a beginning in time.

4. *Creation*. Creation is an act whereby the *entire substance* of a being is brought from nonexistence to existence (*productio totius substantiae ex nihilo sui et subjecti*). Since the entire universe had a beginning and cannot have the sufficient reason for its existence in itself, only an extramundane cause could have given it existence; and since it is here a question of the total substance of the universe, this causal act is a creation.

5. *Creator*. The perfection of the effect manifests the perfection of the cause. Since man, who is a part of the universe, is an *intelligent person*, the creating cause must be an intelligent person; we call Him the Creator or God. Everything in the world proclaims His power, knowledge, and wisdom. Although God is eternal, an *eternal creation* does not seem possible. The duration of a creature consists of successive moments. An eternal duration would involve

an infinite number of successive moments; inasmuch, however, as this number of moments is increased daily, it is finite. An infinite finite number is a contradiction.

6. *The End of the World.* The present world will come to an end. Natural processes are irreversible, due to the conversion of all energy into heat and the diffusion of heat into space. Because of the *Second Law of Thermodynamics* and the *Law of Entropy*, heat eventually becomes unavailable for further work. This constant degeneration of energy will continue and lead to the entropic death of the universe.

7. *Annihilation.* Of itself, the universe will not be annihilated. This follows from the Law of the Conservation of Energy and of Mass. *God can annihilate* the universe; the power which was capable of making the universe pass from nonexistence to existence must also be capable of making it pass from existence to nonexistence. On purely rational grounds, we do not know whether God will eventually annihilate the world. Probably not, because He made matter *naturally indestructible*.

8. *End and Beginning.* The world *could* exist forever in the future. It would not be an 'eternity' in the strict sense. The number of its moments of existence in the future would not be 'infinite,' but a 'finite' number growing indefinitely. Since the units of energy in the world are finite in number, the world cannot have been active from eternity, because that would involve an *actually infinite number* of moments now already, and the finite amount of energy could not have lasted through an infinite number of moments. Hence, the world *began in time*. In every respect, the universe is finite.

GLOSSARY OF TERMS

NOTE: In the case of qualified words, always look for the word or noun qualified. For example: in seeking for *Immanent Activity* look for *Activity*, *Immanent*, etc.

ABSOLUTE. The unconditioned; the ultimate ground of all reality.

ACCIDENT. A being whose nature it is to inhere in a subject (substance) in order to exist; the modification and determination of an existing substance.

ACTION AT A DISTANCE. Philosophically, the action of an agent upon a reagent across an absolute vacuum, so that the agent and the reagent are at a distance from each other without immediate or mediate presence in any manner whatsoever.

ACTIVITY, IMMANENT. An activity by means of which a living being perfects itself and makes itself the goal for the acquired actuality.

ACTIVITY, TRANSIENT. An activity which tends to change another object, distinct from the agent.

AETHER. A kind of imponderable matter assumed to exist in all those parts of the universe not filled by ponderable matter.

AETHERISM. The theory which holds that all matter is a modification of aether.

AEVITERNITY. The duration in existence of a creatural being which of its nature is substantially incorruptible and immortal.

ANNIHILATION. The reduction of the total substance of a being to nothingness.

ATOM. The smallest particle of an element into which the element can be divided chemically while still remaining a portion of this particular element.

ATOMISM. A theory which holds that the ultimate constituents of bodies are atoms.

ATOMISM, DYNAMIC. The atomistic theory which holds that the constitution of bodies, their properties and activities, can be explained by means of the two concepts of homogeneous matter and purely mechanical forces.

ATOMISM, MECHANICAL. The atomistic theory which holds that the constitution of bodies, their properties and activities, can be explained by means of the two concepts of homogeneous matter and applied local motion.

BILOCATION. The Simultaneous presence of one body in two places.

BODY, NATURAL. A body which has a single nature or essence and is an individual substance, so that it is a real unit in the order of being and operation.

CAUSALITY. The positive influence of one thing in the production of another.

CAUSE. That which in any way whatever exerts a positive influence in the production of a reality.

CAUSE, EFFICIENT. That 'by which' something is made; the agent which, through its positive influence, produces something.

CAUSE, FINAL. That 'on account of which' or 'for the sake of which' something is made; the end or purpose of an action.

CAUSE, FORMAL. That 'through which' something is made, thereby becoming specifically what it is.

CAUSE, MATERIAL. That 'out of which' something is made.

CHANGE, SUBSTANTIAL. The transition of one kind of substantial entity into a different kind of Substantial entity.

COMPENETRATION. The presence of two or more three-dimensional or circumscriptive bodies in the same place and space.

COMPOUND. A chemical compound is a substance composed of two or more elements chemically combined in definite proportions by weight.

CONDITION. Something required in order that an efficient cause can act, without contributing any positive influence toward the production of the effect itself.

CONTINGENCY. That attribute of a being in consequence of which its nature or essence does not demand existence.

CONTINUUM. Continuous quantity.

COSMOGONY. The theory of the origin and development of the universe through natural causality.

COSMOLOGY. It is the science of the corporeal universe in its ultimate reasons, causes, and principles.

COSMOS. An assemblage of diverse units so combined as to constitute an integral whole and to function in unison in obedience to some form of control.

CREATION. An act whereby the entire substance of a being is brought from nonexistence to existence (*productio totius substantiae ex nihilo sui et subjecti*).

CRYSTAL. An inorganic structure of molecules arranged in well-defined geometric forms, with definite planes, axes, and angles.

DURATION. The persistence of a being in existence.

DYNAMISM. The theory which holds that the ultimate constituents of bodies are unextended, active forces or unextended mass points with extended forces.

EDUCTION. In the hylomorphic theory, the production of the substantial form out of the potentiality of matter.

ELECTRON. A subatomic particle with a unit negative electric charge.

ELECTRONISM. The theory which holds that all matter is electricity.

ELEMENT. Any material substance which cannot be resolved by ordinary chemical means into two or more simpler substances different in nature from itself.

ENERGISM. The theory which holds that all realities in the universe are but forms of energy, without a material substance which is the bearer or subject of energy.

ENERGY. The capacity for performing work.

ENERGY, KINETIC. The energy which a particle, body, or system of bodies possesses in virtue of its movement.

ENERGY, POTENTIAL. The energy which a particle, body, or system of bodies possesses in virtue of its position or configuration in reference to the position or configuration of other particles, bodies, or systems.

ENTROPY. The mathematical factor which is a measure of the unavailable energy in a thermodynamic system.

EPIGENESIS. See EDUCATION.

ESSENCE. The ultimate reality in a being which makes it to be specifically what it is and distinguishes it from other beings.

ETERNITY. The complete and simultaneous possession of interminable life; the duration characteristic of God's existence.

ETHER. A kind of imponderable matter assumed to exist in all those parts of the universe not filled by ponderable matter.

EVOLUTION, EMERGENT. A doctrine of evolutionary naturalism which maintains that nature is the product of evolution in such a manner that entirely new and unpredictable properties originate through synthesis and thereby form new and higher levels of reality.

EXTENSION. Side-by-sideness of parts in length, width, or depth, or in combinations of these dimensions; dimensive quantity.

EXTENSION, EXTERNAL. The extension of a body in virtue of which its parts are distinct with reference to place and space.

EXTENSION, INTERNAL. The extension of a body in virtue of which its parts have a definite position and order among themselves and in reference to the body as a whole, without any regard to the place or space which they occupy.

EXTENSION, VIRTUAL. The property of a reality consisting of unextended and indivisible parts which occupy a certain field of space through their force.

FORM OF CORPOREITY. According to the theory of John Duns Scotus and his followers, it is the form which makes a particular living being to be 'this body,' whereby 'body' is understood in the sense of 'organized matter' as distinct from the soul as the life-giving principle.

FORM, SUBSTANTIAL. An incomplete, physically simple substance which is the ultimate intrinsic principle of all determination in a body.

GNOSTICISM. A pantheistic form of monism which holds that the world and its contents emanate from God in such a fashion, that in the course of the consecutive emanations things become more and more deteriorated, finally ending in matter.

HYLOMERIC. Consisting of many matter particles.

HYLOMORPHISM. The theory which explains the constitution of 'natural bodies' by means of the dualistic composition of matter and form; matter is indeterminate but determinable, the form is the specifying and determining principle; matter and form are incomplete substances, and their union results in a unitary composite substance, the natural body.

HYLONS. Matter particles, subatomic particles.

HYLOSYSTEMISM. A theory which explains the constitution of the natural body (element and chemical compound) as an atomary energy system, in the sense that the atom of an element and the molecule of a compound are composed of subatomic particles (protons, electrons, etc.) united into a dynamic system working as a functional unit.

HYLOZOISM. The theory which holds that all material substance is endowed with life.

INERTIA. That universal property of matter by which it will remain at rest, or in uniform motion in a straight line or direction ('constant velocity'), unless acted upon by some external force; the property of all bodies to maintain a constant velocity.

INFINITE. Without limit.

INFINITE, ACTUAL. A positive reality without limit.

INFINITE, POTENTIAL. A reality, actually finite, but capable of increase without limit.

INVOLUTION. The theory which holds that all substantial forms are actually precontained in matter from the beginning of creation.

ISOTOPEs. Elements which occupy the same position in the table of elements, because they are identical in chemical behavior, although they differ in their respective weights.

LAW, NATURAL. The rule or norm according to which a being is induced to perform an action or to refrain from an action. Proximately, it is the constant and uniform activity of

a being; fundamentally, it is the natural and inherent tendency of a being to act in a constant and uniform manner.

MASS. The amount of matter in a given volume.

MATERIALISM. A naturalistic form of monism which finds the ultimate solution of all phenomena, physical and psychical, in the nature and activity of universal matter or force.

MATTER. The universal base or substrate of all bodies; the passive principle of diffusion in space; the general principle common to all natural bodies, indeterminate but determinable; the incomplete sub-stance and co-principle which, together with the form, makes the complete substance of the natural body.

MATTER, PRIMARY (PRIMORDIAL). An incomplete corporeal substance, undetermined but determinable, capable of receiving any kind of substantial form.

MATTER, SECONDARY. Informed matter; matter actualized by a form; the matter of an actual, concrete body, as it exists in nature.

MECHANISM. The doctrine which denies finality in nature and explains all occurrences in nature as being determined in a purely mechanical way, so that everything is caused by what it temporally antecedent without having any 'tendency' to produce definite results in the future.

MIRACLE. A perceptible event, forming an exception to the regular course of nature and produced by divine intervention.

MOLECULE. The smallest portion of a compound or, if an element can exist in the free state, of an element.

MONADISM. The Leibnitzian doctrine which holds that the ultimate individual beings are monads; they are partly material and partly immaterial, possess innate power of representation, have no means of cognitional intercommunication, and obtain knowledge corresponding to reality through a divinely pre-established harmony.

MONISM. The doctrine which maintains a single, absolute, self-existent principle of being, the sole constituent of all reality.

MONISM, IDEALISTIC. That type of pantheistic monism which holds that the real and the ideal, thought and thing, nature and spirit, object and subject, world and mind, are ultimately identified in the infinite and absolute Ego.

MONISM, NATURALISTIC. That type of monism which holds that the world originated through natural evolution from some primordial stuff without outside direction, and this primordial stuff is either lifeless matter, or animated matter, or neutral stuff evolving into mind and physical bodies; it seeks to reduce the multiplicity of beings to the essential unity of a single kind of entity.

MONISM, PANTHEISTIC. That type of monism which derives the present world from God or the Absolute as the One-Being through emanation or immanence or determination; it defends the entitative unity of all being.

MOVEMENT. Continuous change.

MULTILOCATION. The simultaneous presence of one body in two or more places.

NATURE. In a being, it is the ultimate source and principle from which all its properties and activities are derived.

NEOPLATONISM. A pantheistic form of monism which holds that the world and its contents emanate from God in such a fashion, that in the course of the consecutive emanations things become more and more deteriorated, finally ending in matter.

NEUTRON. A subatomic particle, equal in mass to the proton and electrically neutral.

OCCASION. A circumstance or combination of circumstances which affords an opportunity for an efficient cause to act.

OCCASIONALISM. The doctrine which denies all creatural causality, so that creatures are only 'occasional causes' for the activity of God, inasmuch as they furnish the occasion for God to produce effects in nature.

PANEGOISM. That type of monism which identifies all reality with the universal consciousness or Ego; a form of absolute idealism, asserting the oneness of all things in the absolute Ego.

PANPSYCHISM. That type of monism which holds that all material reality, in its ultimate analysis, is endowed with psychical powers.

PANSPERMISM. See INVOLUTION.

PANTHEISM. The monistic doctrine which holds that the universe is identical with God; the reduction of God to the universe, or of the universe to God.

PHILOSOPHY. It is the science of beings in their ultimate reasons, causes, and principles, acquired by the aid of human reason alone.

PHOTON. A particle or corpuscle of light.

PLACE. Where a body is.

PLACE, COMMON EXTERNAL. The general position of a body with respect to other bodies at some distance from it.

PLACE, EXTERNAL. The surface of the object or objects immediately enveloping a body, considered as the receptacle of this body's entire volume.

PLACE, INTERNAL. The amount of space contained within the boundaries of the outside surface of a body, considered as the receptacle of the body's entire volume.

POSITRON. A subatomic particle, equal in mass to the electron, with a unit positive electric charge.

PREFORMATION THEORY. See INVOLUTION.

PRESCIENTIFIC. Pre-scientific knowledge is the knowledge of physical objects and phenomena acquired through ordinary sense perception, without the aid of special experimental methods and precision instruments.

PRESENCE, CIRCUMSCRIPTIVE. The presence of a corporeal extended substance in such a manner that it has parts outside parts in the place where it is.

PRESENCE, DEFINITIVE. The presence of a spatially unextended substance in such a manner that it can exercise its activity only within certain limits of space.

PRESENCE, REPLETIVE. The presence of a spatially unextended substance in all space, past, present, and future; the presence of God in the universe or universes.

PRIVATION, In the theory of hylomorphism, it is the lack of a substantial form in primary matter, in so far as primary matter is in a state of proximate aptitude for the reception of a new form.

PROTON. A subatomic particle with a unit positive electric charge.

QUALITY. An absolute accident completing and determining a substance in its being and in its operations.

QUALITY, ENTITATIVE. A quality which modifies a substance in its being, in so far as it is a being for itself.

QUALITY, OPERATIVE. A quality which modifies a substance in its operations, in so far as the substance is capable of activity and change.

QUANTITY. That property of a thing in virtue of which it can be divided into its inherent components, each of which is a single and complete whole.

QUANTITY, CONTIGUOUS. A quantity whose components are in contact at their boundaries.

QUANTITY, CONTINUOUS. A quantity which is uninterrupted in its being, so that the components within it are united by common limits or boundaries.

QUANTITY, DIMENSIVE. Quantity of extension, of magnitude.

QUANTITY, DISCONTINUOUS. A quantity which consists of components, each of which is an entity for itself and has its own complete limits or boundaries; together, they form some sort of unit or whole in a wider sense.

QUANTITY, DISCRETE. See QUANTITY, DISCONTINUOUS.

QUANTITY, INTENSIVE. A quantity of degrees.

QUANTITY, SEPARATE. A quantity whose components are at a distance from one another, so that their boundaries are not in immediate contact.

QUANTITY, SUCCESSIVE. A quantity of components which follow one another in sequence.

QUANTUM. A unit of action or energy, designated as $h\nu$, in which ν is the frequency of the radiation and h (Planck's constant) is a universal constant the value of which is 6.55×10^{-27} ergs.

RADIOACTIVITY. The process whereby certain elements, through their own natural power, spontaneously emit alpha, beta, or gamma rays, or combinations of these rays.

RELATIVITY, EINSTEIN'S THEORY OF. A physico-mathematical theory with reference to motion, space, and time and their measurement.

REPLICATION. The simultaneous presence of one body in more than one place.

SPACE. In a general sense, the three-dimensional container or receptacle of all extended material substances; specifically, abstract extension considered as a receptacle for bodies.

SPACE, ABSOLUTE. The space which is the sum of all real and possible (ideal) space considered as one.

SPACE, IDEAL. See SPACE, POSSIBLE.

SPACE, IMAGINARY. Absolute space, pictured by the imagination as an immense container of bodies.

SPACE, POSSIBLE (Ideal). The space unoccupied but occupiable by extended bodies.

SPACE, REAL. The space occupied by three-dimensional bodies.

SPACE-TIME, In the monistic theory of S. Alexander, the ultimate evolutionary principle or stuff of the world; it has in the beginning no quality except the spatio-temporal quality of motion, but subsequently everything 'emerges' from it into the world we know.

SUBSTANCE. In a scientific sense, an element or chemical compound; in a philosophic sense, a being whose nature it is to exist in itself and for itself, needing no other subject in which to inhere in order to exist.

SUBSTANCE, COMPLETE. A substance which exists in such a manner that its nature demands no further union with a substantial co-principle.

SUBSTANCE, COMPOSITE. A substance which consists of incomplete substantial parts, entitatively distinct among themselves, in such a manner that their union results in a single, unitary nature.

SUBSTANCE, INCOMPLETE. A substance whose nature demands that it be conjoined with some other substantial co-principle, so as to constitute a complete substance.

SUBSTANCE, SIMPLE. A substance which does not consist of entitatively distinct substantial parts.

TELEOLOGY. The doctrine which holds that final causes are operative in nature, that things act according to a definite purpose or design.

TIME. The number of movement according to before-and-after; movement considered in its succession according to before-and-after.

TIME, ABSOLUTE. The time which is the sum of all real and possible (ideal) time considered as one.

TIME, IDEAL. See TIME, POSSIBLE.

TIME, IMAGINARY. Absolute time, pictured by the imagination as a kind of receptacle or stream in which all individual times, actual and possible, have a place.

TIME, POSSIBLE (IDEAL). The time involved in the movements and changes which could, but actually do not, occur in nature.

TIME, REAL. The time involved in the movements and changes which actually occur in nature.

UBICATION. The presence of a body in a place, in so far as a body is precisely in one place rather than in another.

VACUUM. The total absence of a material, three-dimensional substance in the universe.

VACUUM, ABSOLUTE. The total absence of all ponderable and imponderable matter.

VACUUM, RELATIVE. The total absence of all ponderable matter.

VALENCE. The combining capacity of atoms in forming chemical compounds.

AUTHOR'S PREFACE

This book is intended as a text on philosophical psychology for the undergraduate student. It should give him a fairly thorough acquaintance with this department of philosophy.

Since psychology is here treated as a department of philosophy, only those facts and laws of scientific psychology have been incorporated into the text which have a bearing on the philosophical understanding of the ultimate nature of man. Precise laboratory techniques, statistical tables, and mathematical formulae have therefore been omitted as irrelevant to the purpose in view. A general survey of the positive findings of scientific research suffices as a background for the student who is taking an elementary course in philosophical psychology. The scientific material, however, could not be eliminated entirely, because in most cases the undergraduate approaches psychology without any preliminary knowledge of the pertinent scientific facts. Just what scientific data should be taken into the text, is a debatable question; the author hopes he has struck a satisfactory medium.

Bearing the mental equipment of the undergraduate in mind, so that he will derive the greatest benefit from the

text, special attention has been given to the arrangement of the material and to the form of its presentation.

Many psychologists overemphasize the distinctness of the mental functions of man and underemphasize the fundamental unity of man. As a consequence of this attitude man appears as an aggregate of functions and processes. In reality, of course, man is an integral organism expressing himself as a unit in many ways, and the student should never lose sight of this important fact. The integrality of man as an organism consisting of diversified structures, powers, and functions operating as a unit is the leading theme stressed throughout the book. This thought is brought home to the student in the treatment of *The Whole Man* as a vegetant-sentient-rational being.

Some might question the position of the chapters on consciousness and extra-normal mental states in the general arrangement of the material in the book. One must remember, however, that consciousness is an over-all mental state affecting every sensory and rational phenomenon; as such, consciousness cannot be properly understood until all the sensory and rational functions have been described and discussed. Similarly, the extra-normal states of hypnosis, clairvoyance, telepathy, etc., cannot be appreciated in their true significance until the normal sensory and rational states have been described and discussed.

Again, some instructors will miss an extensive treatment of aristotelian hylomorphism in connection with the problem of the union of body and soul. From a psychological standpoint, it is necessary to prove the existence or

nonexistence of a vital principle or soul in the human organism. The theory of hylomorphism, however, is a general interpretation of the constitution of all natural bodies, inorganic and organic, and belongs properly to cosmology. The author has treated the theory extensively in his "*From Aether to Cosmos*," and there seemed no need to repeat the matter in this book.

As for the form of presentation, it has been the endeavor of the author to use non-technical language wherever possible and advisable, with copious examples and explanations to clarify the meaning of obscure terms or facts. While this method tends to make the style somewhat diffuse, the method should enable the student to grasp the difficult subject matter more fully and effectively, and that, after all, is the purpose of every basic text.

It is the fond hope of the author that his psychology text will receive the same kindly acceptance that was accorded his texts in logic, epistemology, ontology, and cosmology.

December 8, 1944

Chapter 1

NATURE AND SCOPE OF PSYCHOLOGY

TO JUDGE FROM THE FREQUENCY OF THE USE OF THE TERM IN ordinary conversation, in magazine articles, and in books, there is hardly any form of human endeavor to which the term 'psychology' is not applied. People speak of the 'psychology' of education, of business, of war, of social classes, of religion, of adolescence, of crime, of individualism, of dictatorship, of football, 'of labor unions, of fashion, and so on. Needless to say, such an application of the term is very broad and loose.

For the psychologist and philosopher, psychology is a special department of human knowledge, a *science*. As such, it has its own proper *subject matter* and its own proper *method of investigation*. It is a science in the strict sense of the word, different from other departments of human knowledge. Unfortunately, however, there is perhaps no other science in which such a divergence of views exists as to what is the proper subject matter and the proper method of investigation as in psychology. The reason for this situation is twofold. On the one hand, man, who is the main object of investigation, is so complex a being, that psychologists cannot seem to agree as to how much of his

being shall be included in the general subject matter of psychology. On the other hand, psychologists are greatly influenced in their decision by the particular type of philosophy which they uphold; it makes a considerable difference, for instance, whether they are materialists or idealists in their outlook on the world.

Subject Matter of Psychology

Considered from the standpoint of its etymological derivation, *psychology* (Gr., *ψυχή*, soul, and *λόγος* discourse, treatise) is the *science of the soul*. Now, the soul, or psyche, is considered to be that in virtue of which an organism lives, the principle of life in plants, animals, and men. Aristotle, the greatest of the Greek philosophers, already conceived it in this manner, namely, as the principle giving life to the body of the organism. Viewed this way, the subject matter of psychology is everything that pertains to the *life of the organism*, whether it be a plant, an animal, or a man. Psychology, therefore, should investigate vegetative, sensory, and rational phenomena as found in plant life, animal life, and human life. Some authors do this, but their number is small.

Most modern psychologists balk at defining psychology as 'the science of the soul.' They consider the 'soul' as a reality which smacks of theology; at best, they contend, its existence cannot be presupposed, and it should, therefore, be excluded as the proper subject matter of psychology. Many prefer to define psychology as the *science of the mind*. The 'mind' is the seat or principle of such phenomena

as seeing, hearing, feeling, desiring, thinking, and willing; in other words, the mind is generally understood to be the ultimate principle or, as others prefer to view it, the sum-total of all the powers, processes, and states found in the sensory and rational life of man. Vegetative functions are not 'mental,' and their investigation does not belong to psychology. Hence, only the 'mental' phenomena characteristic of *animal* and *human* life should be included in the study of psychology.

Others object to the term 'mind.' The term seems to imply something which is the underlying 'bearer' of mental phenomena; it would be merely another name for the questionable reality of a 'soul.' Hence, they prefer to speak of psychology as the *science of consciousness or of the conscious states*. Since some psychologists are convinced that both animals and men possess consciousness, the mental life of *animals and human beings* are the subject matter of psychology. Not all, however, agree with this. They maintain that it is impossible for us to know whether animals are really 'conscious.' Consequently, psychology should restrict itself to the study of the conscious states of *man*. But even this is not entirely satisfactory. Many vital activities of man belong to the 'mental' order, though they are performed subconsciously or unconsciously, as will be seen later; these belong properly, they claim, to the field of psychological investigation. There is, then, no definite agreement among professional psychologists as to the exact subject matter of their science.

Among professional philosophers, too, one finds a division of opinion on this score. Those of the older school of

thought were inclined to look upon psychology as the *philosophy of organic life*; correspondingly, they included the nature of plants, of animals, and of men as integral parts of the subject matter of psychology. Modern philosophers, however, restrict their investigations to the *nature of man*. If they bring the vegetative life of the plant and the sensory life of the animal within the scope of their studies, it is for the purpose of comparison, in order to illustrate some point in connection with the life of man. Most authors omit the discussion of vegetative functions almost entirely, stressing the *sensory and rational* activities of man as the proper field of psychological research. And so it has come to pass that psychology, in its historical development, has narrowed down its subject matter to a great extent.

One must distinguish between two types of psychology — *scientific* psychology and *philosophic* psychology. The attitude of science and of philosophy toward psychological problems is quite different.

Psychology as Science and Philosophy

When we speak of *scientific psychology*, or psychology as a science,' we place it on a par with other positive and exact sciences, such as physics, chemistry, astronomy, biology, etc. It is then considered as a department of knowledge which seeks to discover all pertinent facts by means of observation and experiment, to describe these facts in their proper order, and to establish the general laws according to which these facts occur. Science, so far as possible, uses

quantitative measurements in all its findings and formulates its laws in terms of quantitative measurements.

It is characteristic of the scientific attitude to investigate phenomena by means of immediate observation and controlled experiments, so that everything is based on experience and not on speculative reasoning. The scientist does not inquire into the hidden 'nature' of things; he is satisfied to analyze the phenomena, classify them, and determine their *proximate causes*. Applying these principles of scientific research to psychology, the scientist examines the mental phenomena of sensations, perceptions, emotions, acts of the intellect and will, and so forth, and endeavors to reduce them to their simplest and most fundamental elements or laws. That is why scientific psychology is also called *empirical and experimental psychology*.

Philosophical psychology, or psychology as 'philosophy,' is a branch or department of philosophy and takes its place beside the departments of logic, epistemology, cosmology, ontology, theodicy, and ethics. Philosophy is the science of beings in their *ultimate reasons, causes, and principles*, acquired by the aid of human reason alone. Philosophy endeavors to penetrate beyond the surface of phenomena and uncover the nature and essence which gives rise to such phenomena; thereby it hopes to understand and explain things in a more thorough and satisfying manner. Philosophy accepts the legitimate findings of scientific (empirical, experimental) psychology and then pushes its investigation still farther into the regions of the unknown, thereby attempting to widen the boundary line of

knowledge. Philosophic psychology is thus the extension and completion of scientific psychology.

The scientific psychologist touches many vital problems which he refuses to discuss; the philosophic psychologist finds these problems to be of absorbing interest and cannot resist the desire to solve them. The scientist takes life for granted. But what is life? Whence does it originate? Is it fundamentally distinct from the chemical elements that constitute the body? Is it merely a peculiar kind of material force? Is it the result of a substantial principle? Experimental psychology makes a special study of man's mind in all its moods, states, and operations. However, what is 'mind'? Is it material or immaterial? Is there such a thing as a 'soul'? If the soul exists, is it mortal or immortal? Is there an essential distinction between man and the brute? And what is the origin and destiny of man? No one can say that such problems are unimportant; on the contrary, the solution of these and similar problems are of tremendous importance to man.

The philosopher has no quarrel with the scientist. Both are driven in their research by the same unquenchable thirst for knowledge. If the scientist wishes to restrict the subject matter of his science to the immediately observable phenomena of mental life and their proximate causes, that is his privilege. The philosopher, however, wishes to disclose, if possible, the unobservable *nature* of man manifested by mental phenomena. Who would dispute the right of the philosophic psychologist to delve into the nature of man through the use of his reasoning powers? Reason is just as much an instrument of knowledge as are the senses.

In fact, more so. The scientific psychologist, when he makes an experiment with a subject, uses his senses as instruments of experience to find out the facts of mental life occurring in the subject; and he also utilizes the knowledge of mental facts occurring in his own person. Facts, however, need *interpretation*; they are not self-explanatory. And he interprets these facts by means of his 'reason.' Reason, therefore, is indispensable for the proper understanding of all facts, even in scientific psychology. Hence, the philosophic psychologist is justified in his endeavor to go beyond the limits of scientific psychology by using the powers of speculative or deductive reason for the solution of the deeper problems cast to the surface by scientific investigation.

Man is simply not satisfied with an analysis and classification of the proximate causes of mental facts. The deeper problems of psychology demand a solution, and man cannot help inquiring into the *ultimate causes* which lie behind and beyond the proximate causes. Among all the objects in the universe, the object of greatest interest to man is man. The scientific psychologist should refrain from investigating these ultimate realities in man's being, but the philosophic psychologist must use every means at his disposal in the attempt to arrive at a solution of the fundamental problems which lie in the core of man's innermost nature. He hopes to achieve success in his undertaking by bringing these problems before the piercing scrutiny of reason. Because reason plays such a dominant part in this research into the mysterious nature of man's mental life, philosophic psychology is frequently

referred to as *rational psychology*. Strictly speaking, the terms 'empirical psychology' and 'rational psychology' are misnomers. Both types of psychology are based on experience and as such are 'empirical'; both use reason and as such are 'rational.' It would be better to drop the terms 'empirical' and 'rational' psychology and speak only of 'scientific' and 'philosophic' psychology.

The Method of Psychology

The *general method* employed by psychology in its investigation can be summarized in three words: observe, assume, and prove. It is the method employed by every science.

When a problem presents itself to the psychologist, he must first seek to marshal all the available facts pertinent to the subject matter under investigation. He submits them to careful 'observation,' either by means of personal experience or by means of experiments with various kinds of appropriate instruments. These facts are carefully analyzed, described, and classified. He then makes an 'assumption' or 'hypothesis' as to the possible causes which produce them and the laws which govern their operation; this assumption or hypothesis is provisional in character and subject to revision and modification.

If the hypothesis, when applied to more and more cases of a similar character, gives a good explanation of all the facts, it becomes a 'theory.' The theory becomes a 'law' when it is able to explain invariably all cases, even the apparent exceptions, because a complete explanation is

‘proof’ that the original assumption or hypothesis is the correct explanation of the phenomena in question.

The procedure just described is termed *induction or analysis*, and it is defined as the legitimate inference of universal laws from individual cases. It passes from the particular to the universal, from the complex to the simple, from the phenomena to the underlying general law, from the effect to the cause. The natural sciences are predominantly inductive and analytic in their method of research. The reverse method is *deduction or synthesis*. It is defined as the legitimate inference from the more general to the less general, from a law or principle to a particular instance falling under the law or principle. It proceeds from the universal to the particular, from the simple to the complex, from the logical whole to the logical part, from the general law to the individual cases, from the cause to the effect. The mathematical and philosophical sciences are predominantly deductive and synthetic in their method. No science, however, is exclusively inductive or deductive. Both methods must be used, depending on the circumstances. Psychology, in its empirical and experimental portions, uses the inductive method, while it uses the deductive method largely in its philosophical portions.

There is a *special method* employed by psychology, and it is twofold in character: subjective and objective.

The *subjective* method is that of *introspection*. Introspection is the method of studying mental phenomena by means of the internal observation of experience on the part of the individual person. Conscious mental states exist

in the mind, and they can be observed and examined only by the mind turning its attention upon its own states. This immediate observation and examination of one's own internal mental states and activities is what is meant by 'introspection.' I alone am capable of knowing what sensations, emotions, ideas, and volitions are present in my mind, so far as actual observation is concerned. Even when the scientific psychologist makes use of instruments and other experimental devices, in the final analysis he must rely on introspection, because he must interpret the facts in the conscious mental acts of his own mind.

The *objective* method is the method employed to gain information about the mental states and processes of man through means other than introspection. More is needed for the building of a science than the information acquired from a single individual's mental experiences; this personal information must be supplemented by data obtained from outside sources.

Among these outside sources, a few are of special value to the psychologist. First of all, he can study the information of *other minds*, whether communicated to him in spoken or written words, and thereby compare their observations and experiences with those of his own mind obtained through introspection. The study of the various *languages* may contribute appreciable data, because language is the external expression of mental processes and ideas. *Animal psychology*, too, can be very helpful. Animals, as will be established later, are sensory beings pure and simple, while man is partly sensory and partly rational. The study of animal behavior should enable us to draw a sharper line of

distinction between the sensory and rational activities and powers in man; the knowledge gained should assist us indirectly in acquiring a better knowledge of man himself. There are many things in *biology* and *physiology* which are useful in understanding the psychical activities in man, because sensory functions are vital processes depending on specific organs. Man has a body as well as a mind, and the two are closely united in everything man does. An extensive knowledge of the nervous system should be a considerable aid in acquiring a better knowledge of how man's mind can come into contact with the physical world. *Abnormal psychology*, since it is based on pathological conditions, shows by contrast what the normal conditions are. Oftentimes, the absence of a particular function, because of disease, enables us to distinguish clearly between one mental power and another. *Psychiatry*, especially, throws a strong light on many psychical processes. Information of a most valuable kind is obtained from the experimental science of *psycho-physics*, that branch of psychology which studies the relations between mental and physical processes by investigating the response to stimuli and the perception of physical magnitudes. Such experiments are conducted in various psychological laboratories.

No single method is perfect. The combination of various methods, so far as they can be applied, will enable the psychologist to arrive at a substantial body of facts which can be molded into a real and reliable science.

Psychology and Cognate Sciences

It is usual to distinguish between the 'material' and the 'formal' object of a science. The *material object* of a science is the general object with which it occupies itself in its investigation. The *formal object* of a science is that special phase or aspect of the general object which forms the subject matter peculiar to this particular science and which distinguishes it from all other sciences.

The 'material' object may be the same for a number of sciences. The bodies existing in the world are the material object of the sciences of astronomy, physics, chemistry, crystallography, etc.; each of these sciences, however, studies the same bodies from its own characteristic standpoint. Organisms, or living bodies, are the material object of biology, botany, zoology, and psychology; nevertheless, these sciences are distinct from one another, because each one views and treats this general object under a different aspect. The various sciences thus have much in common, but they also differ among themselves. It is necessary, therefore, to distinguish psychology from a number of kindred sciences.

Among the *natural* sciences which have much in common with psychology we find biology and physiology. There is, however, a difference. *Biology* treats of life in general, as found in all organisms; psychology treats mainly of the 'mental' life of organisms, particularly of man. *Physiology* studies the functions of life present in the organs, tissues, and cells of living beings, exclusive of mental functions; psychology studies the mental life of organisms, while physiological matters are brought into the discussion only incidentally.

Among the *philosophical* departments, logic, epistemology, cosmology, and ethics have a certain kinship with psychology. Due to their formal object, however, they are distinct sciences. *Logic* examines the intellectual activities of the human mind from the standpoint of correct thinking; psychology studies the entire field of human mental states and activities, including sensation, perception, emotion, intellection, and volition. *Epistemology* is concerned with the validity or truth-value of human knowledge; psychology, with the nature of the human mind and its various operations. *Cosmology* investigates the constitution of bodies in so far as they are natural physical bodies; psychology treats of the human body only in so far as it is an integral part of the nature of man. *Ethics* examines human actions as qualified by the attributes of right or wrong and thus restricts itself to voluntary actions; psychology examines human action in all its manifestations of mental life.

We thus see that the same material object is the general subject matter of a number of sciences, making them more or less related. From the standpoint of their formal object, however, they vary to a considerable degree.

The Whole Man

The confusion of opinions about the proper 'subject matter' of psychology makes it difficult to formulate an exact definition of psychology. Everything depends on the viewpoint of the individual psychologist or of the school of psychology to which he belongs. No matter what viewpoint

anyone takes, there is bound to be objections against it from many sides.

There is also a difference of opinion as to the proper 'method' to be employed in psychological investigations. The school of *behaviorism* claims that introspection is not a legitimate method. It rejects or ignores 'mind' and 'consciousness' altogether and contends that psychology should restrict itself exclusively to the study of the external behavior of animals and men. This is an extreme view which is rapidly passing out of the picture of psychology. Most modern psychologists admit that the objective method of studying behavior can and does contribute valuable data, but they are convinced that introspection must always be the main method of psychological investigation.

Notwithstanding this confusion, the psychologists of all shades agree, both in theory and in practice, that the *chief purpose* of psychology is the better understanding of *man*. Historically, psychology had its origin in the study of man as a part of philosophy; only in relatively recent times has psychology divorced itself from the philosophical study of man in general and become a science in its own right. It was a misfortune that a sharp line of demarkation was drawn through man's being, separating body and mind in such a fashion that they were considered to be opposing realities. This division should never have been made.

Irrespective of all philosophical theories, man is a *single, unitary being*. He is a single, unitary, *living* being. And it is the distinctive feature of man that he comprises within his being the vegetative functions of plant life, the sensory functions of animal life, and the intellectual and volitional

activities of rational life. Though we observe in man three distinct types of life, these three types are merged together into an *integral organism* which assimilates, grows, senses, feels, thinks, and wills. Man, as each of us knows from personal experience, is one.

Psychology, as a branch of philosophic science, should not cut man into segments and study one or the other segment exclusively. To treat man in this manner is to do violence to man as an integral organism. *The whole man* should be studied in all the phases of his life and being. Only in this way will it be possible to obtain a full and comprehensive knowledge of what man really is, and that should be the ultimate purpose of the psychological study of man.

Philosophy seeks to bring every kind of being within the scope of its investigation. Cosmology treats mainly of inorganic beings. *Organisms*, beings endowed with organic life, should be treated in a special department of philosophy, because inorganic and organic substances are the two natural divisions of bodies existing in the universe. The organisms are represented by the three great classes, plants, animals, and men. In as much, however, as man possesses the vegetative life of plants and the sensory life of animals, it is logical to include the peculiarities of their type of life in the treatment of man as the embodiment of all three types of life in a single organism. Man, especially in his mental life, will be the *chief object* of psychological investigation, but plant life and animal life should not be pushed aside entirely.

Hence, *the whole man*, both in his activities and in his fundamental nature, is here proposed as the *primary object* of study for the psychologist who is also a philosopher. As for the method of investigation, any and all methods are acceptable, provided they furnish us with data which throw light on man's complex being and enable us to grasp in some measure the workings of his inner constitution. The modern scientific psychologists will in all probability disagree with us. In as much, however, as these same psychologists cannot agree among themselves as to what should be considered the proper subject matter and method of psychology, we feel justified in taking the position here indicated.

If we now attempt a *definition* of psychology, we may define psychology as the *philosophic science of the life of the human organism*. It is a 'science,' i.e., a reasoned body of truths arranged into a system of knowledge. It is a 'philosophic science,' i.e., a science which, based on the established findings of empirical and experimental psychology, draws conclusions as to the ultimate principles, reasons, and causes which account for the proximate causes of phenomena. It is the philosophic science of 'the life of the human organism,' i.e., it studies the life of the whole man as an organism, especially in its sensory and rational features, so as to arrive at an understanding of the inner constitution and nature of man.

In using the terms 'life' and 'organism,' we accept them in the meaning given to them in the biological sciences. This meaning is, of course, only provisional for the present. Everybody admits the fact that man, like the plant and

animal, is an 'organism' and that he possesses 'life.' The precise philosophical meaning of these terms will become clearer in the course of our study.

The Value of Psychology

Without question, man is the noblest and most intelligent being on earth and, so far as we are able to judge, in the universe. Since every kind of knowledge is of value in some form or other, the knowledge of man should be the most valuable of all. It should be far more valuable than the knowledge of nonliving beings and of plants and animals. Hence, psychology is more important than chemistry, physics, mathematics, astronomy, geology, biology, botany, and zoology, and other natural sciences. We are speaking here, of course, of the knowledge about created things in the visible universe.

Psychology studies the *knowledge process* step by step in its development, from the reaction of the sense organs to the external stimuli, in its passage through the internal senses, and in its transition over into the intellect, until it reaches its completion in the formation of ideas, judgments, and acts of reasoning. The various *mental powers* active in the acquisition of sensory and intellectual knowledge will be studied in detail. A knowledge of these powers will be of great value for all the *sciences*, because they are the result of the knowledge process of man's mind. Similarly, such an acquaintance with the knowledge process and the powers of the human mind is essential to the entire system of

education, for without it proper methods of education cannot be devised.

The psychological study of the *will* and of voluntary action is of paramount value for *law, ethics, and sociology*. Our treatment of individual responsibility, of domestic and social relations, and of international rights and duties will have to undergo essential modifications, if we must come to the decision that the human will is not truly free.

From a *personal* standpoint, the question of the existence, spirituality, and immortality of the *individual soul* is of vital interest to everyone, depending on whether the question must be answered in the affirmative or negative, because the answer will influence the direction of each one's entire life.

The first part of the book follows the general lines of empirical and experimental research. The second part seeks to determine the ultimate nature of man as an organism.

Summary of Chapter I

Psychology is a science, with its own proper subject matter and method of investigation.

1. *Subject Matter of Psychology.* Etymologically, psychology means 'the science of the soul.' Many modern psychologists look upon psychology as 'the science of the mind'; others, as 'the science of consciousness.'

Among philosophers, some consider psychology to be 'the philosophy of organic life,' including within its subject matter the life of plants, animals, and men. Others restrict the subject matter to the nature of man in his vegetative, sensory, and rational life. Some restrict it entirely to man's sensory and rational life.

2. *Psychology at Science and Philosophy.* As a science, in the modern sense of 'scientific psychology,' it analyzes mental phenomena, classifies them, and determines their *proximate causes*. 'Philosophical psychology' seeks to penetrate beyond the surface of phenomena to the *ultimate reasons, principles, and causes*, so as to uncover the nature and essence which gives rise to such phenomena.

Scientific psychology is also termed 'empirical' and 'experimental,' while philosophic psychology is often called 'rational.'

3. *The Method of Psychology.* The general method employed is induction, or analysis, and deduction, or synthesis. Both must be used, but scientific psychology is predominantly inductive and analytic, while philosophical psychology is largely deductive and synthetic.

The *special method* is twofold, subjective and objective. The *subjective* method of introspection studies mental phenomena by means of the internal observation of experience on the part of the individual person. The *objective* method seeks information about the mental states of man through means other than introspection. Such pertinent information is supplied by other minds, languages, animal psychology, biology, physiology, abnormal psychology, psychiatry, and psycho-physics.

4. *Psychology and Cognate Sciences.* We must distinguish between the 'material' and the 'formal' object of a science. The *material* object is the general object with which it occupies itself; the *formal* object is that special phase or aspect of the general object which forms the subject matter peculiar to this science and which distinguishes it from all other sciences. Since the material object may be common to a number of sciences, psychology is related to the natural sciences of biology and physiology and to the philosophical sciences of logic, epistemology, cosmology, and ethics. It differs from them, however, in its formal object.

5. *The Whole Man.* The *chief purpose* of psychology is the better understanding of *man*. Man is an *integral organism*, comprising within his being vegetative, sensory, and rational life. Hence, the whole man is here proposed as the primary object of study. We may therefore *define* psychology as *the philosophic science of the life of the human organism*.

6. *The Value of Psychology.* The study of the knowledge process and of man's mental powers is of value for all

sciences and for the entire system of education. The study of the will is of paramount value for law, ethics, and sociology. The question of the existence, spirituality, and immortality of the individual soul is of vital interest to everyone.

Chapter 2

MAN: AN ORGANISM

MAN IS AN ORGANISM. LITERALLY, AN 'ORGANISM' IS A BEING which consists of, or possesses, organs, and by an 'organ' we understand a part or structure adapted for the performance of some specific function or functions. Biologically, an *organism* is an individual constituted to carry on the activities of life by means of parts or organs more or less separate in function but mutually dependent. It is in this biological sense that man is an 'organism.'

Man is, therefore, a living bodily being, just as a plant or an animal is said to be a living bodily being. Men, animals, and plants form the three great kingdoms of living beings in our universe, so far as our knowledge goes, and, since they possess life, they are radically distinguished from inanimate, or nonliving, beings, such as chemical elements and chemical compounds.

All these types of being have much in common. Chemical functions are found in plants, animals, and men; the functions of plants are found in animals and men; and the functions of animals are found in men. It will be advisable, therefore, to analyze and compare these various types of

being, in a factual manner, and thereby obtain at least a summary knowledge of man as an organism.

Living and Nonliving Matter

It is not our purpose here to introduce a philosophical discussion on the difference between living and nonliving matter. The difference between these two types of being is recognized by all to be a fact beyond dispute. Without going into elaborate details, the *main characteristics of living matter* are as follows:

First, *organization*. Living matter is organized. Living beings possess organs or structural parts distinct from one another, each of which has a specific function to perform. Organization is found in unicellular as well as in multicellular plants and animals. An amoeba, for example, possesses diverse structures within its single cell-body, and these various structures (organs, organelles) perform diverse functions.

Second, *irritability*. Living matter responds to changes in the environment (such changes are called 'stimuli') by change in shape, production or cessation of movement, or other activities of their organs or parts. Living matter does not receive the influences of surrounding objects and energies in a passive manner, but reacts to them in a specific way, each plant and animal reacting differently to the same stimulus.

Third, *metabolism*. In biology and physiology 'metabolism' is the technical term which designates the processes in plant and animal cells involved in the

construction and destruction of living tissue during the course of the activities of life; it consists of the chemical changes occurring in living cells, by which the energy is furnished for carrying on vital activities and new material is assimilated for the maintenance and repair of the individual plant or animal. The essential processes of life are produced in and by the 'protoplasm.' Protoplasm is the physical basis of life. It is the essential substance constituting the body and nucleus of the cells of plants and animals. Ordinarily, protoplasm is a practically colorless, semi-fluid substance, filling the body of the cell and containing a large amount of water in which fine granules are suspended. Its physical structure is not well known, though it is now recognized by all biologists to be heterogeneous in character and is considered to be different in different types of cells and in different types of organisms. Chemically, it is an extremely complex compound, the composition of which is still obscure.

Metabolism has a twofold aspect. The one is constructive, and is termed 'assimilation' or 'anabolism'; the other is destructive, and is called 'disassimilation' or 'katabolism.' *Anabolism* is a synthesis, a building up of the living protoplasm through the absorption of nutritive materials and the changing of these materials into the living substance of the cell; the simple elements are thereby united into complex organic compounds, and in this chemical process energy is stored for future use. *Katabolism* is a destruction, a breaking down of the protoplasmic material; the protoplasm is decomposed and oxidized, the energy necessary for the activities of life is

thereby liberated, and the waste is excreted. In this double process, therefore, dead matter is first changed into living substance, and then living substance is changed back again into dead matter.

Fourth, *growth* and *reproduction*. By 'growth' we understand the progressive development of a cell, organ, or organism from its earliest stages to full maturity. No cell, or organ, or organism comes into existence complete and fully matured in size and structure. It develops gradually through the intussusception of nutritive material. By 'reproduction' we understand the process by means of which cells produce new cells and plants and animals produce new plants and animals of the same kind. Even in the case of new plants and new animals, however, they originate from single cells, so that all reproduction is ultimately a matter of cell reproduction. Ordinary cell reproduction in multicellular plants and animals (for example, in a tree or a cat) is simply 'growth' of the individual. In unicellular plants and animals (for example, in a *gloeocapsa* or an *amoeba*) this cell reproduction always results in the generation of a new individual. In the higher forms of plants and animals the reproduction of new individuals requires specialized cells whose sole function is the generation of offspring. All reproduction, whether of cells in ordinary growth or of individuals through generation, is thus the result of some form of cell division. In order to grasp the significance of these facts, it is necessary to understand the nature of the cell and of cell division.

Notwithstanding their many differences, all cells have certain features in common, which makes them fundamentally alike. It is thus possible to give a diagrammatic representation of a *generalized cell*.

Fig. 1. Generalized Cell. The two main parts are the nucleus and the cytoplasm. The cytoplasm is the protoplasmic body of the cell, as distinguished from the nucleus. — The nucleus with its contents is the essential organ of the activities of metabolism, growth, and reproduction of the cell; in most cases, the nucleus is a well-defined body, but in some types of cells its contents are distributed throughout the cytoplasm. — The nucleolus is a small nucleus usually found within the body of the regular nucleus. — Chromatin is a deeply staining nuclear material which is the physical basis of heredity; it appears in the nucleus as a network of irregular arrangement. — The framework is a sort of semisolid protoplasmic network distributed throughout the cytoplasm of the cell. — Vacuoles are cavities or vesicles containing a watery fluid. — Plastids are small bodies of specialized protoplasm, active in metabolic changes. — Metaplastids are lifeless undigested particles or waste material. — A chondriosome is a semifluid body. — Oil drops and yolk globules are nutritive material. — The centriole is a specialized mass of protoplasm which develops into an aster or starlike figure in cell division. — The centrosome is a minute protoplasmic body lying in the centriole.

Not all cells contain all the parts shown in the illustration. Essential, however, to every cell is the *nucleus*;

it is the bearer of vital activity, and without it the cell would die. Among the structural elements of the nucleus, the 'chromatin' material plays an important part in the life cycle of the cell. When a cell is about to divide, whether for the purpose of growth or of generation, this chromatin material assembles itself into a strip or thread and then breaks up into separate particles called 'chromosomes.' These chromosomes contain the 'genes' which are the main factors in heredity. During cell division, each chromosome splits evenly into two portions, temporarily doubling the number of chromosomes; one half remains with the parent cell, the other half goes to the daughter cell. Since the total number of chromosomes is constant and specific for each type of plant or animal (for example, the drosophila, or fruit fly, has eight chromosomes in each cell), every cell in the body has the same number of chromosomes. The entire process of cell division is termed mitosis ('the formation and movement of threads') or *karyokinesis* ('movement of the nucleus'). (See Fig. 2.)

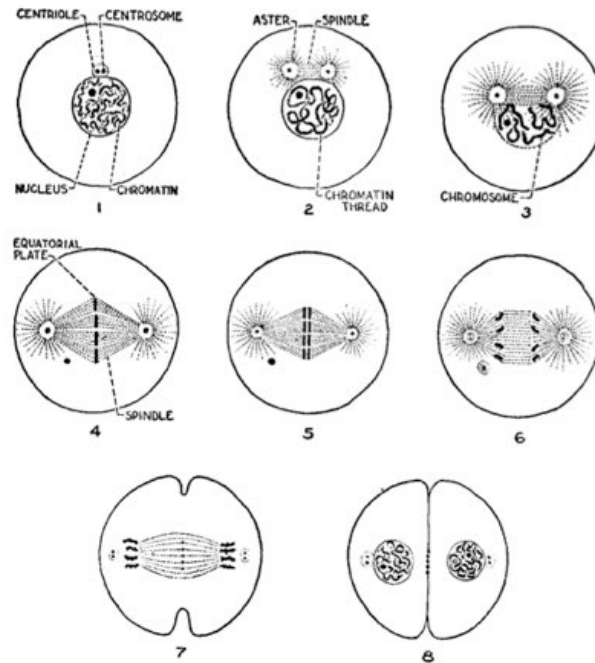

Fig. 2. Mitosis, or Cell Division. 1. The cell in its resting stage. — 2. The beginning of mitosis. The two centrosomes separate and move apart, each enclosed in an aster or starlike figure. A spindle of protoplasmic filaments is formed between the two asters. The chromatin arranges itself into a thread. — 3. The chromatin thread breaks up into loops, the chromosomes. — 4. The chromosomes are caught up by the spindle and arranged circularly in the equatorial plate. — 5. The chromosomes divide longitudinally, doubling their number. — 6. One half of the chromosomes are drawn toward one aster, the second half toward the other aster. — 7. The cell body begins to divide. — 8. The chromosomes dissolve into chromatin. The cell body has undergone a complete division so that the original cell now consists of two daughter cells. For the sake of simplification, the diagram represents but four chromosomes.

In the *generation* of new individuals, a portion of the parent's body is separated or set aside, and this portion then develops into the offspring. When the offspring originates from a single parent, it is an 'asexual' reproduction; examples are cleavage ('fission') and budding

(‘gemination’). Most multicellular plants and animals, however, especially those of a higher type, generate their offspring by means of ‘sexual’ reproduction, in which the new individual originates from the union of the female egg cell and the male sperm cell; these sex or germ cells are called ‘gametes.’ If these eggs and sperms retained their full number of chromosomes and passed them on to their offspring, the latter would have a double number of chromosomes in each body cell. Thus, the first drosophila, or fruit fly, would transmit 16 chromosomes to its offspring; the second generation would receive 32; the next, 64; and so forth. In the long run this would be disastrous to the individuals and the species. As a matter of fact, of course, this multiplication of chromosomes does not occur. It is avoided by a particular kind of cell division in the gametes, called maturation division.’ In maturation division one half of the number of chromosomes of the germ cell pass out of the body of the cell and form a so-called ‘polar body.’ In this manner the number of the chromosomes of both the egg cell and the sperm cell of the parents is halved; and when these two cells unite to constitute the fertilized ovum, the original number of chromosomes is restored, so that the first cell of the offspring contains the same number as the cells of the parent bodies. From this point on, the first cell of the offspring divides and multiplies according to the process of ordinary mitosis. (See Figs. 3 and 4.)

Fifth, *individuality*. Every organic being consists of heterogeneous parts — elements, chemical compounds, cells, tissues, organelles, and organs. Each part has its own peculiar function. All parts and all functions, however, are

not there for their own sake, but for the sake of the organism as a whole; they are mutually dependent and conspire toward the welfare of the individual plant and animal as a totality, a unit. It is the individual which counts, not so much the parts. All functions are, strictly speaking, functions of the individual, and the parts and organs are merely the means through which the individual carries out its varied activities. The individual plant and animal is, in all truth, much more than the sum of the parts which make up its body. This distinctive and constant individuality is the reason why scientists are able to make such a complete classification of plants and animals into varieties, species, genera, etc.

These are the main characteristics of living substance in general. Nothing similar to organization, irritability, metabolism, growth, reproduction, and individuality is found among the combinations of elements and compounds in inorganic nature.

The Cell and the Crystal

Some have argued that the cell is but a type of crystal, or, at any rate, that the crystal is so similar to the cell that there is no fundamental difference between them. A resemblance exists, but it is altogether superficial. A comparison between the crystal and a unicellular plant, which is the lowest form of life, should prove fruitful in establishing the *great difference* between living and nonliving matter.

First of all, the *composition* of crystals is very different from that of cells. The material of crystals consists either of

pure elements (for example, carbon or sulphur) or of chemical compounds which are found everywhere in nature (for example, sodium chloride or potassium sulphate); and the whole crystal is composed entirely of such elements and compounds. Not so the cell. There is a considerable diversity of material in the cells; organic compounds of various types are present; and this material is not distributed uniformly throughout the body of the cell, but is different in different parts.

Then, there is a difference of *structure*. A crystal is formed by the symmetrical juxtaposition of the atoms and molecules along geometrical lines and sharp angles; it is a latticework, each part of which is a constant repetition of every other part; and it is characterized by extreme rigidity. The cell, however, possesses a body made up of distinct parts, heterogeneous in structure, none of which is a mechanical repetition of another; its nucleus manifests great complexity of structural detail; the protoplasm shows a manifold differentiation; the entire cell material is relatively soft, pliable, and rounded in contour.

Again, the *growth* of a cell is radically diverse from that of a crystal. A crystal grows through the mere superposition of layer upon layer of identical material upon the outside surface, leaving the interior of the crystal untouched and unchanged. The cell, on the other hand, grows by means of intussusception and assimilation of foreign material, and this material is broken down and remade into organic compounds, the like of which is found nowhere in nature except in the organism.

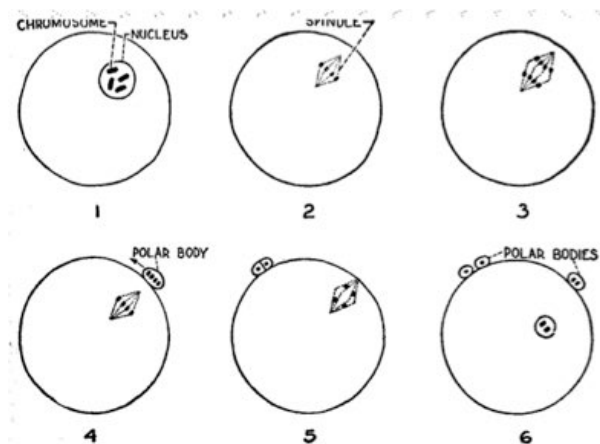

Fig. 3. Maturation Division of Gamete or Germ Cell. 1. The germ nucleus moves toward the periphery of the cell. — 2. The chromosomes arrange themselves into a spindle. — 3. The chromosomes divide. — 4. One half (4) of the chromosomes pass out through the cell wall and form the first polar body. — 5. A new spindle is formed. The remaining chromosomes arrange themselves in pairs. — 6. One pair of chromosomes passes out and forms the second polar body. Only two chromosomes (one half of the original number) are left in the mature gamete. — For the sake of simplification, the diagram represents but four chromosomes.

Furthermore, there is a difference of *activity*. The only activity which occurs in a crystal is the atomic and molecular activity which builds the crystal and retains its geometrical shape; the crystal as a whole has no activity. The cell, however, is definitely active throughout the period of its existence; metabolic changes take place at all times. The cell reproduces itself, giving rise to new cells and to new individuals, something a crystal never does. The cell produces many by-products, such as alkaloids, essential oils, and many other organic substances, while the crystal never produces anything.

Finally, the *duration in existence* is totally different for the crystal and the cell. The crystal is a rigid and

permanent thing and, if left to itself, will remain indefinitely in existence as a crystal; some crystals are, without doubt, thousands and probably millions of years old. A crystal can be dissolved and recrystallized, and this reversible process can be repeated times without number. The cell, as a cell, has a definite span of existence; after a certain length of time, it ceases to exist of its own accord and decomposes.

A superficial comparison might show a resemblance between a crystal and a cell, but a closer scrutiny reveals the fact that they are totally different: the crystal is simply dead matter, while the cell is a living being.

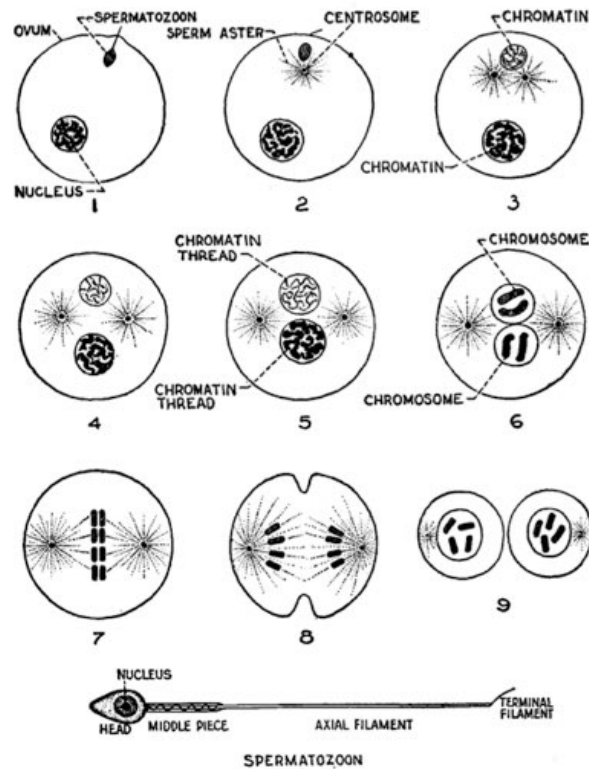

Fig. 4. Fertilization. 1. The spermatozoon (sperm, male gamete) enters ovum (female germ cell, female gamete). — 2. The centrosome of the spermatozoon becomes visible. An aster is formed. The head of the sperm cell swells, and the nucleus of the ovum grows larger. — 3. The chromatin framework of the sperm nucleus becomes visible. The centrosome doubles. — 4. The centrosomes move apart, each to opposite sides of the cell. The chromatin material of the sperm nucleus has completed its framework stage. — 5. The nuclei of the spermatozoon and of the ovum are now equal in size and condition. — 6. The chromosomes are formed in the two nuclei, alike in number. (The chromosomes of the spermatozoon nucleus are shaded, while those of the ovum are in solid black.) — 7. The spindle is complete, and the chromosomes divide longitudinally and equally. — 8. Four chromosomes (two paternal and two maternal) move toward the left aster, and four to the right aster. The cell body begins to divide. — 9. The division is complete. Two cells are formed, each containing four chromosomes (two paternal and two maternal), the original number found in each of the ordinary body cells (somatic cells). Multiplication of cells now occurs through regular mitosis. — For the sake of simplification, the diagram represents but four

chromosomes.

Man: A Vegetant Organism

Plant life is the lowest form of life known on the globe. Negatively, a plant is a living being devoid of cognition; no organs, which might serve for perception, are discernible, and no functions manifest real knowledge of any kind. Positively, a plant is an organism which possesses the functions of *nutrition, growth, and propagation*. Although the plant has many diversified functions, they are subservient to these three, which are characteristic of a plant as such. Since nutrition, growth, and propagation are vegetative activities, a plant is a vegetant organism pure and simple.

Man, too, is a vegetant organism, because man, like a plant, feeds himself, grows, and propagates.

The *elements* used in the process of human nutrition, in the main, are: oxygen (O), hydrogen (H), carbon (C), nitrogen (N), iron (Fe), calcium (Ca), sulphur (S), phosphorus (P), magnesium (Mg), sodium (Na), chlorine (Cl), manganese (Mn), copper (Cu), and potassium (K); some others are also found occasionally. These elements and their compounds serve a double purpose in the organism: the production of energy and the maintenance of the various tissues and organs throughout the body. These elements, when used as food by man, come in the form of *organic compounds* and are supplied by plants and animals. The three main groups of food substances are the carbohydrates, the proteins, and the fats. Certain mineral

substances, too, are necessary, and also vitamins and hormones.

Before these organic substances can be used for energy or maintenance, they must be broken down and transformed through chemical change. This transformation is carried out in the *gastro-intestinal tract* through the agency of various secretions, elaborated by the salivary glands and the glands of the stomach, of the liver, of the pancreas, and of the intestinal walls. The enzymes, 'present in these secretions, perform an important function in this connection. They are organic catalysts. A catalyst is a substance which by its mere presence among other substances changes the rate of chemical reactions, without itself undergoing a change in the process. Some organic compounds are manufactured by chemists in the laboratory, but such reactions are obtained only by using high temperatures and pressures; in the organisms the enzymes bring about such reactions with utmost ease and speed. The chemist, for example, cannot change glucose to galactose, but the body does this readily with the help of enzymes. The action of enzymes is specific for certain types of substance; they may either decompose or synthesize compounds.

After the transformation of the food is complete, it is ready to be assimilated. *Resorption* occurs primarily in the small intestine. The liquified food particles, now broken down into very small molecules, pass through the intestinal wall. Most of this material is carried by the portal vein to the liver and from there by means of the hepatic veins to the inferior *vena cava*, near the right auricle of the heart, where it enters the blood stream; the rest is carried by the

lymph channels through the thoracic duct to the subclavian vein, where it also enters the blood stream. In this manner the food particles become a part of the blood, flow to the heart, and are pumped to all tissues of the body. Each cell, tissue, and organ then assimilates whatever it needs for its own particular purpose.

Until an organism reaches the full stature of its maturity, it is in a condition of *growth*. Man, too, as a vegetant organism, is subject to growth. He begins life as a single cell, the fertilized ovum, which normally attaches itself to the wall of the uterus of the mother, and then receives nourishment from the maternal blood. During the period of gestation, practically all the members and organs of the child are completely formed. Man's body is thus 'fearfully and wonderfully made,' before it sees the light of day in birth. The body continues to grow and develop until the early twenties. During all this time the ordinary processes of life continue uninterruptedly: energy is stored, used, and restored in an endless cycle; cells and tissues are built, torn down, and rebuilt in unceasing activity; and all the while the growth of the body goes forward to full maturity. From that point on maintenance of bodily structure is the chief function of metabolism.

Reproduction in man, as in all living beings, is a marvel of activity and structural design. The conception of the child occurs when the gametes or germ cells, namely the female ovum and the male sperm, fuse so as to bring about a union of the chromosomes of the two gametes. The specific number of chromosomes in the somatic, or body, cells of man is 48. In order that the child, beginning life with the

fecundated ovum, have this same number of chromosomes in each cell of its body, it is obviously necessary that the number of chromosomes in the parent germ-cells be reduced to one half, or 24. This is accomplished in each by means of a maturation division.

Maturation division takes place in both gametes, but not in the same manner. The female germ cell possesses 46 ordinary chromosomes and a special pair called 'X' chromosomes; the male germ cell contains, besides the 46 ordinary chromosomes, a pair consisting of one 'X' chromosome and a much smaller one designated the 'Y' chromosome. In the development of the *male* gamete, maturation division proceeds in the following manner. Forty-six chromosomes form 23 pairs of chromosomes, but the 'X' and 'Y' chromosomes do not form a real pair. The 23 pairs divide vertically (not longitudinally, as in ordinary cell-division); 'X' and 'Y' remained unchanged. The male gamete now divides into two cells, one cell having 23 chromosomes and the 'X' chromosome and the other 23 chromosomes and the 'Y' chromosome. These two cells again divide, but this time the chromosomes divide longitudinally without pairing. We now have four cells, and the result of this division is: two cells each possessing 23 ordinary chromosomes and an 'X' chromosome, and two other cells possessing 23 ordinary chromosomes and a diminutive 'Y' chromosome. Of these four sperm cells one develops and grows to full size to become the spermatozoon, or mature male fecundating cell, while the other three degenerate and disappear. The *female* ovum also undergoes a maturation division, in order to reduce the 48 chromosomes

to 24; however, no further division takes place, and the result will always be that the mature ovum contains 23 ordinary chromosomes and one chromosome.

SINCE EVERY FEMALE HAS AN 'XX' pair of chromosomes in its cells and every male an 'XY' pair of chromosomes in its cells, biologists have constructed a theory to determine the sex of the child. The surviving spermatozoon may contain either an 'X' or 'Y' chromosome. Depending on the nature of this chromosome, the child will be

either female or male: if it is an 'X' sperm, it will be a daughter; if a 'Y,' a son.

According to this theory, it will be seen, the sex of the child is already determined at conception; later developments merely bring out the characteristics of the respective sexes.

These are, in basic outline, the chief features of life in man as a vegetant organism. In reality, of course, the vegetative activities taking place in man's body are immensely varied and complex.¹

Man: A Sentient Organism

An animal is radically different from a plant, both anatomically and functionally. A plant is restricted in its functions to the vegetative activities of nutrition, growth, and reproduction. The animal body exercises these activities, modified to suit its type, but over and above these vegetative activities it possesses a nervous system of some sort with an activity peculiarly its own. Man is an animal organism and as such has a nervous system and performs nervous functions.

The *basic unit* of the nervous system is the neuron, or nerve cell. The neuron has a number of parts. The 'cell body' consists of nerve protoplasm and takes care of the nutrition of the entire neuron. The 'nucleus,' like the nucleus of every other kind of cell, has its location in the cell body and is the functional center of all nerve activity in the neuron; it also is the bearer of the specific characteristics of the neuron. The 'axon' is a prolongation of the body of the nerve cell, typically single and long, terminating in short branches relatively far from the cell body; the axon, together with its coverings, forms the nerve fiber, and the axon is the axis cylinder of such a nerve fiber. The 'dendrites' are protoplasmic structural processes of the neuron; they branch repeatedly and taper rapidly, terminating near the cell body. As a rule, dendrites conduct nerve impulses toward the cell body, while axons conduct nerve impulses away from the cell body. The 'end brushes' are the many minute fibrils which extend from the axons. The 'neurilemma' is the outer sheath enclosing a nerve fiber. Some axons are enveloped in a sheath of myelin, or fatty

tissue, and this is called the 'medullary sheath' or 'myelin sheath.'

Every nerve cell, or neuron, possesses the properties of *excitability and conductivity*. The nerve tissue is 'excitable' or 'irritable,' that is to say, it has the property to react to a stimulus; and a stimulus is the influence of free energy (chemical, thermal, radiant, mechanical) applied to irritable tissue. In response to a stimulus, an impulse is transmitted along the nerve fiber; the property of a nerve fiber to transmit such an impulse is termed 'conductivity.' This impulse may travel from the periphery inward to the central portion of the neuron; then we speak of a 'receptor neuron,' and such fibers are 'sensory' or 'afferent' fibers. Or, the impulse may travel from the central portion of the neuron to the periphery; this is an 'effector neuron,' and fibers of this type are 'motor' or 'efferent' fibers. Since the nerve impulse can travel in only one direction, depending on whether a nerve fiber is of the afferent or efferent type, nerves are said to possess 'polarity.' The endings of afferent nerves, specially adapted to the reception of peripheral stimuli, are called 'receptors'; if these endings terminate in definite organic structures, such as the eye or ear, they are termed 'receptor' or 'sense organs.' The endings of efferent nerves terminate in glands or muscular tissue, effecting a stimulation there, and such nerve endings are styled 'effector organs.'

EVERY NEURON IS A DISTINCT ANATOMICAL UNIT; HENCE, NERVE cells, in relation to each other, are not continuous, but

Fig. 5. Synapse of Afferent (Sensory) Neuron and Efferent (Motor) Neuron.

contiguous. Contact with other neurons is made by junctions or *synapses*, and the stimulation of one neuron by another is through the synapse from end brush to dendrites. The synapse is therefore defined as the place at which a nervous impulse passes from the axon of one neuron to the dendrites of another. Whether or not an impulse shall pass from one neuron to another depends on the momentary state of the synapse. It is assumed that the resistance to the conductivity of the nerve impulse is greater in the synapse than in the neuron,

and this resistance varies with conditions. Since the axons act as a stimulating apparatus and the dendrites as a receiving apparatus, the nerve impulse can travel only in one direction, namely, from axon to dendrite; this is the so-called *Law of Forward Conduction*. Whenever a neuron is stimulated, it either does not respond at all, or it responds with the maximum output of which it is capable, no matter what the strength of the stimulus; this is the *All-or-None Law* of nerve activity.

The rate of speed with which the impulse travels through a nerve is about 100 meters per second. The nature of the *nerve impulse* is not definitely known. All nerve action,

however, is accompanied by *electra-chemical* phenomena. For this reason many biologists consider the nerve impulse to be entirely and solely electro-chemical in nature, in the sense that chemical changes in the tissues produce electrical pulsations of varying frequency and regularity in the nerve fiber. It must be noted, however, that the rate of speed of the nerve impulse, being far below the speed of electricity, militates against such a view. Whatever the nature of the impulse itself, electrical phenomena are always present. Attaching the two electrodes of a galvanometer to a nerve fiber and stimulating the nerve end, the needle of the instrument swings first to one side and then to the other; this fact indicates that an electrical current has passed. At the same time it is noticed that the active part of the nerve tissue is electro-negative, as compared with the part which is inactive. The frequency of these pulsations differs with the intensity of the stimulation, but all have the same magnitude in a given fiber. These pulsations are called 'action currents or 'action potentials' of the nerve.

After a nerve has been stimulated, a certain interval of time must elapse before another reaction can set in, just as if the nerve were a battery that had been discharged and must recuperate by recharging. During the period of recuperation the nerve resists stimulation, and this period is styled the 'refractory phase.' When this refractory phase is passed, there follows a brief period, called the 'phase of hyper-excitability,' in which the nerve reacts to a stimulus of minor strength. From a *chemical* standpoint, nerves in action consume oxygen, give off carbon dioxide, and

produce heat. Nerves, therefore, become fatigued through activity and demand rest periods after prolonged stimulation.

While it is true that each neuron, or nerve cell, is a physiological unit, independent of the other neurons, it is also true that these neurons do not stand and operate in isolation. By means of synaptic junction points the nerve impulses travel over a multitude of paths from fiber to fiber. In this manner the nerves together form a complete and integral *nerve system*. Spread throughout the whole extent of the body, fibers form nerves, nerves combine into trunklines, trunklines unite into minor systems, and minor systems merge into one grand system which services the entire sentient organism. In man there are two main systems of nerves: the *cerebrospinal system* and the *autonomic system*. Since the student should have at least a rudimentary knowledge of these systems, a summary of their structures and functions will be given in the next chapter.

NERVE ACTION CULMINATES IN *SENSE KNOWLEDGE*. THIS KIND OF cognition is a property of animal life. The animal organism possesses certain structures which mediate a knowledge of the conditions within the animal body itself and of conditions and things external to the body. Such structures are termed sense organs or 'receptors.' Various types of *sense knowledge* occur in man.

Man, by means of the *tactual or somesthetic sense*, experiences pressure, temperature, pain, hunger, thirst,

nausea, bodily equilibrium, bodily movements, and combinations of these states. The knowledge acquired thereby enables him to safeguard the health and integrity of his body. Since the messages are conveyed by the nerve fibers connected with end-organs located in the skin, in the viscera, and in the muscles, joints, and tendons, man obtains a fairly accurate mental picture of the relative position and condition of his members. The sense of *taste* acquaints him with the savors of various objects, and the sense of *smell* with their odorous qualities. While a certain amount of pleasure is derived from taste and smell, fundamentally these senses are protective in character; they enable man to recognize and distinguish things which are useful or harmful for his well-being. Through the sense of *hearing* man perceives sounds emanating from objects in the outside world. Distant objects hereby come within the range of man's cognitive powers. Some sounds have a purely natural significance, such as the voice of wind and water, the calls of birds and animals; others receive a meaningful significance through man's own contriving, like the music of an orchestra, a song, or human speech. Perhaps the most distinctively external cognitive sense of man is that of *sight*. Practically the whole world becomes a picture book to man's mind through his eyes. He sees the colored panorama of the earth by means of his unaided sight, while with the aid of microscope and telescope he penetrates into the mysteries of the infinitesimally small and of the immeasurably vast.

Besides these so-called 'external' senses, man has *internal* senses. His *central or synthetic sense* [historically

called *the common sense* - ed.] combines the data of the various external senses into a composite perception. Not only does he experience the activity of the separate senses, but he can localize them in his body. He perceives the yellowish color and spherical shape of a certain object with his eyes, feels its soft and rough texture with his hands, tastes its sweet flavor with his palate, and smells its fragrant odor with his nostrils; his central sense unites these distinct and mutually independent data into a harmonious sensory whole and calls this thing of diversified qualities an 'orange.' Even when the objects which stimulate his senses are absent, he can make them present again in an image within his mind, reproducing in an imaginal way their many qualities by means of his *imagination*. Past events are recalled and recognized as past, so that their exact position in time and place is located and dated; recognition is the work of his *sensory memory*. Finally, man experiences certain unlearned tendencies or drives or dispositions toward or away from certain specific objects or activities in given situations; these drives are the *instincts*, and they are directed mainly toward the preservation of the individual and of the race.

Appetition is the second main activity of man's sensory life as an animal organism. It follows sensory knowledge. Man does not only 'know' objects in a sensory way; he also desires them and strives for them, fears them and flees from them, loves them and hates them. Emotional states, such as joy, sadness, hope, despair, courage, and anger, are involved in appetite; also feelings, as pleasure and displeasure.

There is a very important point to be noted in this connection. Man's body consists ultimately of ordinary chemical elements and compounds. But his body is not just a mass of lifeless, inert chemicals, because these elements and compounds are transformed into living, organized materials which thereby become an integral part of the body in its vegetative functions of nutrition, growth, and reproduction. Nor do the vegetative functions run an independent course in man's body, as if man as a vegetative being and as a sensory being performed vegetative and sensory functions separately along parallel lines. On the contrary, the vegetative organs not only carry out their proper functions of nutrition, growth, and reproduction like a plant, but also build, feed, repair, and reproduce nerves, nerve tissues, and organs of the body as a sentient organism. On their part, the nerves, nerve tissues, and organs stimulate and control the vegetative organs in their respective functions for the general welfare of the body as a unified whole. And the same chemical elements that are utilized in the vegetative organs and functions are also utilized in the sensory organs and functions. Man is, therefore, *one being with an integration* of materials, structures, and functions, with activities of a chemical, vegetative, and sensory character, all welded into a *vital unit organism*.

Man: A Rational Organism

Man is a *rational organism*. Man is 'rational,' because he possesses reason. Rationality, in man, implies *cognitive and*

appetitive powers.

Intellectual cognition manifests itself in a threefold function: the formation of ideas, of judgments, and inferences.

Ideas are the intellectual representations of things. Ideas of things are quite different from the sense images of these same things. Sense images are concrete, particularized, individualized; ideas are abstract, generalized, universalized. An example will clarify this. I see a man and note that he is tall and slender, has a height of six feet two inches, weighs 190 pounds, with a white skin, brown eyes, and brown hair. All these features and attributes are concrete, particularized, individualized; and they are different for different human beings. On the other hand, my idea of 'man' is that he is a 'bodily, living, sentient, rational substance'; in other words, this man is a 'rational animal,' and the definition fits not only this man but every human being, whether infant or adult, whether male or female, whether white or black, whether tall or short, whether heavy or light, etc. Ideas are, therefore, class ideas, universals. The sense perceives a man in all his *concrete individuality*, with all the peculiar traits and characteristics which make him to be 'this' man and differentiate him as an individual from every other. The intellect, however, in its idea apprehends him in those essential attributes which he has *in common* with all other human beings, leaving aside all the individualizing and differentiating marks peculiar to himself. so that the content of the idea is *universal*, applicable to the individual and the whole class of individuals.

A judgment is an act of the intellect affirming or denying one idea of another. I compare, for example, the idea 'tree' with the idea 'plant' and recognize the fact that they agree; I then pass the affirming judgment, 'A tree is a plant.' Or, I compare the idea 'tree' with the idea 'animal' and see that they disagree; thereupon I pronounce their disagreement in the judgment, 'A tree is not an animal.' If my affirmation or denial in the judgment corresponds to reality, it is a true judgment; if not, it is false. Judgments, therefore, contain *truth or error*. Just as ideas are intellectual representations of 'things,' so judgments are intellectual representations of 'facts': they claim to express the truth about reality as it actually is in itself.

A *reasoning* process or *inference* is used when the mind does not perceive the agreement or disagreement between two ideas by a direct comparison of the two, so that it can make an immediate judgment about them. In order to judge that 'The sky is cloudy,' all that is necessary is that I look at the heavens and see the clouds. 'Can diamonds burn?' Looking at a diamond, or comparing the ideas 'diamond' and 'burn,' will not settle the question. If, however, I can bring in a third known idea with which, upon comparison, I find the two ideas to agree, then I am justified in saying that they agree with each other. Casting about for an idea which could mediate between the ideas 'diamond' and 'burning,' I find that 'carbon' is the substance of which diamonds are made and also that carbon burns. I now argue: 'Carbon is combustible; a diamond is carbon; therefore, a diamond is combustible.' Inference or reasoning is defined as the mental process by which, from certain truths already

known the mind passes to another truth distinct from these but necessarily following from them.

Volition is another phase of man's rational life. *Rational appetite* follows intellectual knowledge, just as sense appetite follows sense knowledge. The power of rational appetite is called the *will*, and the exercise of this power is volition or willing.

It is characteristic of human volition that an intellectual *motive* must precede its exercise. The intellect views a certain object or course of action under the aspect of something 'good.' This 'good' to be acquired is the motive which influences the will to determine itself to act. We experience the fact of *choosing* in the exercise of our will. There is the choice between action and non-action, between one type of good and another type of good, and between various sets of means to attain the same end. The good desired may belong to the physical order, as food and sense pleasure; but it may also belong to the intellectual and moral order, as truth and virtue. One of the most important features of rational volition is that of moral right and moral wrong and the consciousness of personal *responsibility* in choosing between the two. It is the conviction of mankind that the will possesses the liberty of self-determination in such matters, so that man is said to have a *free will*.

Man: An Integral Organism

Man is a living being or organism. He is, similar to the plant, a vegetant organism. He is, similar to the animal, a sentient organism. He is also — and this is a prerogative

peculiar to himself — a rational organism. From each viewpoint, he possesses distinct types of functions. It would, however, be a serious error to draw too sharp a line of demarkation between these types of functions, so as to consider man as a composite being consisting of three organisms somehow united into one. On the contrary, man is an *integral organism*, a single unitary substance which possesses vegetative, sensory, and rational functions.

It has already been pointed out that the selfsame substance performs vegetative and sensory functions. The nerves and senses support and control the vegetative organs in their functions, and the vegetative organs supply the foods which nourish and sustain the nervous system. And so, too, the same organism, which is both vegetant and sentient, is, in the case of man, also rational. There is a complete *integration* of the three types of life — vegetative, sensory, and rational — in man as a single organism.

That man is not three organisms united into one, but a single integral organism with three distinct types of vital functions, is evident from the testimony of our *consciousness*. Nothing is clearer to us than the facts manifested to us by our consciousness. Man is aware that he has a 'body' and a 'mind.' He is aware that he has intellectual knowledge and rational volition. He is aware that he has perceptions of sight, hearing, etc., and that he has sense appetitions and emotions and feelings. Finally, he is conscious of *self*, of his own *Ego*, in all these functions, and he recognizes his own self as the *subject* of these functions, as the agent who performs them and in whom they occur. He is also aware that these functions differ

among themselves, while he, in whom they take place and in whom they inhere as their subject, is *integrally one and indivisible*. These facts are expressed by him in phrases which leave no place for doubt, like the following: 'I think,' 'I will,' 'I see,' 'I hear,' 'I feel,' 'I am hungry,' 'I experience pain,' 'I have pleasure,' 'I eat,' 'I am growing,' 'I am losing weight,' 'I am healthy,' 'I am ill,' 'I walk,' 'I am lying down, and so forth. The same Ego, therefore, considers itself to be the one underlying subject of vegetative, sensory, and rational functions.

It is most important to bear the integrality of man in mind during all subsequent discussions. It will be necessary to treat of the various mental activities of man as if they were isolated entities; but one must never lose sight of the fact that all are *interconnected and mutually interdependent*, and that they are merely various closely related functions of one being, one substance, namely, of man as an *integral organism*.

Summary of Chapter II

Man is an *organism*, i.e., an individual constituted to carry on the activities of life by means of parts or organs more or less separate in function but mutually dependent.

1. *Living and Nonliving Matter*. There is a fundamental difference between living and nonliving beings. Living substance manifests *organization, irritability, metabolism, growth, reproduction, and individuality*. None of these features are found in nonliving matter.

The Cell and the Crystal. Though there exists a superficial resemblance between them, they differ radically in composition, structure, method of growth, activity, and natural duration in existence.

2. *Man: A Vegetant Organism*. Like the plant, man feeds himself, grows, and propagates. *Nutrition* is the preparation and assimilation of nourishing materials in the gastro-intestinal tract. Until he reaches the full stature of maturity he is in a condition of *growth*; growth takes place through the multiplication of the cells through mitosis. The *reproduction* of man by propagation occurs when the gametes or germ cells, after a maturation division has reduced the number of chromosomes by one half, unite to form the fertilized ovum.

3. *Man: A Sentient Organism*. The animal, as distinct from the plant, has a *nervous system* with *sensory functions*. The basic unit of the nervous system is the 'neuron'; it possesses excitability and conductivity. There are 'sensory' or 'afferent' nerves, and also 'motor' or

‘efferent’ nerves. The endings of afferent nerves, terminating in definite organic structures for reception of external stimuli, are called ‘receptors or sense organs’ (eyes, ears, etc.). In man there are two main systems of nerves: the *cerebrospinal* system and the *autonomic* system. *Sense Knowledge and Appetition*. There are various types of sense knowledge in man: tactual or somesthetic, taste, smell, hearing, sight; central or synthetic sense, imagination, memory, and instinct. *Appetition* is the striving toward or away from objects. It is accompanied by various emotions and feelings.

4. *Man: A Rational Organism*. Rationality implies intellectual cognition and rational appetite. *intellectual* cognition manifests itself in a threefold function: the formation of ideas of judgments, and of inferences. The power of *rational appetite* is the ‘will,’ and the exercise of this power is ‘volition’ or ‘willing.’ The object of the will is the ‘good.’ An important feature of rational appetite is that of ‘moral good’ and ‘moral wrong’ and the consciousness of ‘personal responsibility.’ This is based on the conviction of mankind that man has a ‘freewill’ possessing the liberty of self-determination.

5. *Man: An integral Organism*. Man is a living being or organism. He is, similar to the plant, a vegetant organism. He is, similar to the animal, a sentient organism. He is also rational organism. He is, however, not three organisms some how united into one, but an *integral organism*, a single unitary substance which possesses vegetative, sensory, and rational functions.

Chapter 3

THE NERVOUS SYSTEM

PSYCHOLOGY IS MAINLY INTERESTED IN THE MENTAL LIFE OF man, whether it be on the intellectual or sensory level. Since the intellectual operations are based to a very great extent on the sense operations, and since the latter are dependent on the nervous system, it is imperative to give at least a cursory description of the nervous system. The latter consists of two main subsystems: the *cerebrospinal system* and the *autonomic system*. Though independent of each other to a certain degree, they are organically one.

The Spinal Cord

The *spinal cord* is a mass of neurons and nerve fibers, enclosed in the skeletal housing of the vertebral column or spine, and extends from about the base of the skull to the end of the spine. The brain and adjacent organs are but the natural extension and amplification of the cord.

Through indentations on the ventral and the dorsal side, the cord is divided into two connected segments, the *right and left segments*. The inside of each segment consists of gray matter containing the nerve cells, while on the outside

each segment consists of white matter composed of bundles of nerve fibers emanating from the cells.

Two *pairs* of nerves emerge from the cord between each of the vertebrae, one from the right side and one from the left. One part of such a pair comes from the dorsal side, and the other part from the ventral side, of the cord; both parts unite, after going separately a short distance, to form a single bundle of fibers. The part emerging from the dorsal side of the cord consists of *afferent* (sensory) nerves; the ventral part consists of *efferent* (motor) nerves. After uniting into a single bundle, the afferent and efferent nerves travel together to various parts of the body and then separate to terminate in their respective organs. There are thus two opposing *conduction paths* from the periphery of the body (i.e., the region in which nerves terminate) to the spinal cord, and *vice versa*: afferent (sensory) nerves send impulses (sensory messages) from the peripheral organs to the spinal cord, and efferent (motor) nerves send impulses (motor messages) from the spinal cord to the peripheral organs. The *intercommunication center* is the cord itself, where a synaptical contact is made between the sensory

Fig. 6. Cerebrospinal Nervous System.

The figure shows the relative position of its major parts.

and motor nerves. The two sets of fibers (afferent and efferent), upon juncture in the spinal cord, are also in contact with all other fibers of the spinal column and of the brain by means of *connecting* fibers extending from the brain down the entire length of the spinal cord.

The cell bodies of the efferent (motor) nerves are located in the ventral horns of the cord. The afferent (sensory) nerves show a marked difference in this respect; their cell bodies are not located in the cord itself, but are massed together as *ganglia* outside the cord and at a short distance from it.

The *function* of the cord is clear. It serves as a communication center between receptors and effectors coming from, and leading to, the various parts of the body, and also between them and the higher centers of knowledge and control situated in the brain. A linkage is thus established between the autonomic and cerebrospinal systems.

The Autonomic System

As the name indicates, this system of nerves is 'independent,' 'a law unto itself,' 'self-acting.' While it is not true that this system is completely independent of the central nervous system as a whole, its independence of function is sufficient to warrant the name. The connection between this system and the spinal cord and brain is mainly indirect. The *autonomic system* is that part of the peripheral nervous system regulating responses not directly under voluntary control, especially responses

concerned with digestive, circulatory, respiratory, and reproductive activities.

Numerous ganglia of this system are connected with the central nervous system through the mediation of *preganglionic fibers or white rami*; they are medullated neurons, and their cell bodies are located in the brain stem and cord. Other fibers are the *postganglionic fibers or gray rami*; they are unmedullated neurons, whose cell bodies are located in the autonomic ganglia, and whose fibers activate various organs in the body. These fibers are efferent, not afferent, in their functions.

Fig. 7. Cross Section of the Spinal Cord.

The autonomic system is made up of two mutually antagonistic sections: The *sympathetic* (vegetative, visceral) system and the *parasympathetic system*. The sympathetic system is situated in the thoracic and lumbar regions. The parasympathetic consists of two parts: the *cranial*, located in the cranial or head portion of the spine, and the *sacral*, located in the sacral or extreme lower portion of the spine. (See Fig. 8.)

It will be noted that the sympathetic and the parasympathetic systems send fibers to the same visceral and glandular organs; they also innervate the smooth (non-voluntary) muscles of the body. While the one type of fibers acts as an 'accelerator' for some organs, the other type acts as a 'retarder' or 'brake' for the same organs, depending on whether the one type or the other is in the ascendancy.

Under normal conditions, each type has the dominant control over certain portions of the bodily mechanism, but gives way to the other type under particular circumstances. Ordinarily, the activities of both systems are balanced, so that their co-ordination provides a stable, harmonious functioning of the entire organism.

The *parasympathetic or craniosacral* section of the autonomic system regulates the digestive and eliminative processes and the reproductive functions. These operations are accompanied by the more gentle states of feeling and emotion. The *cranial* fibers affect the pupil and lens of the eyes, the circulation in the head glands, the secretions of saliva and gastric juices; they retard heart action, promote the contraction of bronchial tubes, and in general stimulate the muscles of the alimentary tract in their regular functions. The *sacral* fibers control the processes of the rectum, the bladder, and the generative organs in their non-voluntary functions. The parasympathetic nerves are dominant when the organism is mostly in a state of repose.

Fig. 8. Diagram of the Sympathetic and Parasympathetic Nervous System.

The *sympathetic* section of the autonomic system is more in the nature of an 'emergency' mechanism, when danger is imminent or when injury has been sustained, and its operations are accompanied by strong emotions and feelings. In the presence of danger the organism must either flee or fight; in either case energy must be released freely and liberally, and fatigue products must be eliminated quickly. This condition demands that certain processes be accelerated, that endocrine secretions be poured into the blood stream, and that the blood itself flow rapidly and fully to the peripheral organs, leaving the digestive processes in abeyance for the time being. The effects of the sympathetic, therefore, involve the following phenomena: the heart movement is accelerated, the bronchioles of the lungs are dilated in order to furnish a larger supply of oxygen through deeper breathing, the smooth muscles of the intestinal organs are slowed down in their action and their blood vessels are constricted, the secretion of adrenalin and the secretions of the sweat glands are noticeably increased, and sugar is released from the liver and discharged into the blood for the production of more energy.

The autonomic system is made up of nerve fibers and ganglia. Two chains of ganglia, like strings of beads, lie on either side of the spine, interconnected among themselves and also connected with the spinal cord. From both these trunks of ganglia fibers ramify to the periphery, some uniting in other ganglia before reaching the visceral organs and others going directly to their destination.

Emotional states greatly influence the activities of the sympathetic and parasympathetic sections of the autonomic

nervous system. On the other hand, such activities, when pronounced, are reflected in various moods of a psychic character.

The Brain Stem

The *brain stem* is a prolongation and amplification of the spinal cord. It comprises a number of distinct organs. Starting from the upper end of the spinal cord and ascending into the skull to the brain proper, these organs are: the medulla, the pons, the cerebellum, the midbrain, and the thalamus.

The *Medulla Oblongata* or *Bulb* begins just above the first spinal nerve and is an enlargement of the spinal cord. The medulla is about two and one half centimeters in length. Structurally it is similar to the cord, except for the fact that it contains much more gray matter or nerve nuclei than the cord, due to the origin of a number of nerve tracts in the medulla itself. These tracts lead outwardly to peripheral receptors and effectors and upwardly to higher centers of the brain. Some ascending nerve paths of the cord pass through the medulla to upper portions of the brain; others end in the medulla and form synaptic junction points with centers located here. The medulla, therefore, acts to a great extent as a relay center between cord and brain. It is also the main 'decussation' or crossing point of the sensory and motor paths which come from below and enter the brain. Fibers from the left side of the body cross over to the right hemisphere of the cerebrum (large brain), while fibers from the right side cross over to the left

hemisphere. Some nerves, however, such as the facial nerves, enter the brain above the medulla and do not decussate. It thus happens that an injury to the left hemisphere will paralyze the left side of the face and the right side of the body. The medulla plays an important part in regulating the rhythmic processes of circulation, digestion, respiration, etc., and it also serves as the correlating center for reflexes between certain sense organs and muscles.

The *Pons Varolii* (named after Varolio, an anatomist living in the 16th century) is a further enlargement of the brain stem, situated immediately above the medulla. It consists of the projection fibers which pass through the medulla upward to the large brain (cerebrum) and also of a large number of commissural or connecting fibers which lead to the two hemispheres of the small brain (cerebellum). For a long time it was assumed that the function proper to the pons was to serve as a connection between the two hemispheres of the cerebellum; hence the name 'pons' or 'bridge.' The function of the pons is more extensive. It has a role in the innervation of autonomic nerves and also in the innervation of the facial muscles. Most important is its function of linking the cerebellum with the controlling centers of the cerebrum.

The *cerebellum* is located above the medulla and behind the pons. It is divided into two parts, called the 'hemispheres,' by a medial fissure, and it is composed of gray and white matter. The gray matter contains the cell bodies; the white matter, the axons. The gray matter is situated at the outer surface or 'cortex' of the cerebellum,

while the white matter is inside and underneath. The cortex has numerous fissures and convolutions. The cerebellum receives sensory impulses from the tendons, muscles, and joints of the body, and also from the organs of postural equilibrium located in the inner ear. It is thus the center, to a large degree, of equilibrium reactions and of coordination in the execution of complex movements which require training and skill. Its general function, therefore, is muscular tonus and coordination. The activities of the cerebellum do not enter consciousness.

The *Midbrain* and *Thalamus* occupy the topmost position of the brain stem and are thus located in the center of the entire brain between the hemispheres of the cerebrum. The *midbrain*, the smallest portion of the brain in man, has four 'colliculi' or protuberances on its dorsal side and cerebral 'peduncles' or fiber bundles on its ventral side. The interior portion of the midbrain is composed of numerous nuclei and is called the 'tegumentum.' The colliculi probably control auditory and visual reflexes. In general, the midbrain is concerned with instinctive bodily impulses of various kinds. The *thalamus*, a bilateral organ with parts to the right and left of the stem, has three distinct portions, the dorsal thalamus, the hypothalamus, and the sub-thalamus. The dorsal thalamus is a center for the reception and relay of sensory impulses; its nuclei are associated with all the sense organs (smell, probably, excepted), passing their impulses on to the cerebral centers. Not much is known of the functions of the hypothalamus and sub-thalamus, but they are probably of a motor or efferent character. The general function of the thalamus seems to be the regulation

of reflex connections for emotional responses through association with visceral reactions. Many authorities consider the thalamus to be the primary center of pain sensitivity.

The brain stem, as will be seen from these few remarks, is an important complexus of organs. Its position between the spinal cord and the cerebrum is indicative of its function in the general scheme of the nervous system as a whole; it is a midway station for sensory and motor impulses traveling to and from the cerebrum from all parts of the body.

The Cerebrum

The *cerebrum*, or large brain, is the structure of the central nervous system which lies above the brain stem. It represents the final enlargement and amplification of the spinal cord and brain stem and fills out the greatest portion of the skull. More nerve matter is found in the cerebrum than in all the rest of the body. Its weight is approximately 50 ounces, consisting of nerve nuclei, dendrites, and axons. It is estimated that the number of neurons in the cerebrum runs literally into the billions.

The full number of neurons or nerve cells is already present at *birth*. Many of these, however, are not fully developed, but are embryonic in character; these embryonic neurons are called *neuroblasts*. The neuroblasts must be developed into mature neurons before they can function as integral parts of the nervous system. No doubt much of this development occurs as the result of the natural

growth of the organism; but it is very probable that development of neuroblasts into neurons also results from the conscious effort of mental activity, and this development proceeds up to middle life and even far beyond. The number of neuroblasts, however, is so large that only a portion of them reach maturity in any human being.

Fig. 9. Mesial Section of the Human Brain.

The *structure* of the cerebrum is very complicated. It consists of *gray* and *white* matter. The gray matter is composed of nerve cells and forms the outer surface of the cerebrum; this outer surface is termed the *cortex*, and its depth does not exceed 4mm. The white matter is composed of nerve fibers and forms the tissue beneath the cortex. The cortex has a remarkably large surface area (about 20,000 sq. mm.), because it is furrowed by many fissures (*sulci*) and convolutions (*gyri*), Which provide a maximum of area in a minimum of space.

There are three relatively large and important *fissures*.

The *median* fissure divides the entire cerebrum from front to back, and the two resulting symmetrical halves are the right and left 'hemispheres.' The fissure of *Sylvius* extends horizontally just above the ear. The fissure of *Rolando*, or central fissure, begins at the center on top and runs downwards and laterally in front of the fissure of Sylvius. This division enables us to distinguish four roughly definable regions or *lobes*: frontal, parietal, occipital, and temporal. The frontal lobe is situated in front of the Rolandic fissure; the *parietal* lobe, immediately behind the Rolandic fissure; the *occipital* lobe, at the back of the cerebrum; the *temporal* lobe, below the fissure of Sylvius.

Fig. 10. Side View of the Right Hemisphere of the Human Brain.

The cerebral *cortex* or *neo-pallium*, as it is also called, consists of a number of *layers* in its structure of gray

matter. These layers are not actually separated from one another; they form an uninterrupted mass of cells, but these cells are of different kinds, and a stratification among them is noticeable. The outermost layer is composed of terminal filaments, dendrites, and nerve cell bodies; then follows a layer of pyramidal cells (cells which have the shape of 'pyramids'); then, a granular layer; the latter is followed by a layer of large pyramidal cells; and, finally, situated at the bottom of the cortex, a layer of cells of various sizes and shapes, called polymorphic cells. The layers above the granular section are presumably associated with psychic functions, and those below with organic functions.

Three types of nerve fibers are found in the brain. There are various motor and sensory areas in each of the cerebral hemispheres. Masses of nerve fibers reach out in complicated patterns, connecting all such areas with one another. These fibers are the *association* fibers. The two hemispheres are symmetrical in structure, each practically a duplicate of the other. They do not act in isolation, but in conjunction; and, in order to effect this conjunction, the motor and sensory areas of the one hemisphere are interconnected by fibers with the corresponding motor and sensory areas of the other hemisphere. Such fibers are called the *commissural* fibers. Where they meet in crossing, a dense body or mass of fibers is formed between the hemispheres, serving as a sort of bridge, and this mass of fibers is termed the '*corpus callosum*.' A third type consists of the fibers of *sensory and motor nerves*. The sensory nerves come from the spinal cord and brain stem and

ascend into the cerebrum, making connections between the sense organs and the cortex. The motor nerves leave the cortex and descend into the brain stem and spinal cord, and from there pass out to the musculature. These ascending and descending nerve fibers are the *projection* fibers. Not all fibers pass down into the spinal cord; some of them, the twelve cranial nerves, leave the base of the brain directly and terminate in various parts of the head. Among them are the nerves of smell, sight, and hearing.

Fig. 11. Bottom View of the Human Brain.

The structure of the cerebrum indicates very plainly that it is a marvelously complicated mechanism of nerve cells and fibers, designed as the supreme organ of coordination and correlation for the entire organism. And such is, indeed, its purpose and function.

Localization of Function

It has always been known that injuries to the brain affect sense knowledge and motor reactions. Gradually the fact was recognized that definite areas of the cerebrum control definite functions. The phrenologists used this fact to develop the theory that every function is located in a specific area of the brain. While this theory of *phrenology* has been definitely disproved, it is true that certain *areas* of the brain are the *localization centers* for sensory and motor functions. It would be erroneous, however, to locate such functions exclusively in these centers or areas. The structure of the brain, with its many sensory and motor nerves connecting various parts of the cortex, in itself is a strong presumptive argument that such functions are distributed, even though certain areas are the regular centers of control. The fact is now established that oftentimes, when a part of the brain is damaged, another area will take over the functions usually controlled by the part that has suffered injury. The cerebrum thus acts as an *integrating organ of coordinated function*, each part being involved to a certain degree in the functioning of every other part.

Fig. 12. Diagram of the Right Hemisphere
With Localization Areas.

The actual centers of sensory and motor functions comprise a relatively small portion of the total area of the cortex. The major portion of the cortex is apparently concerned with the coordination and association of sensory and motor impulses and with the mental processes of conscious knowledge and behavior.

The *functional* areas of the brain (see Fig. 12) are fairly well known. In the main, they are as follows. The frontal lobe contains the *motor area*. It is located anterior to the central fissure of Rolando. Beginning from the top of the cerebrum and moving downward, toward the ear, we encounter the motor centers, respectively, of the legs, the trunk, the arms, the head, and the tongue and mouth. Immediately posterior to the central fissure lies the *somesthetic area* which responds to sensory impulses emanating from various conditions of the body in general. The *visual area* is located in the occipital lobe or rear portion of the cortex. The *auditory area* is situated in the temporal lobe, below the fissure of Sylvius. The *olfactory* and *gustatory areas* (smell and taste) have their general location centrally at the base of the brain. All these motor and sensory areas merge into *association areas*; the function of the latter consists in the correlation of the impulses received in the various motor and sensory areas, thereby enabling the brain to effect complex responses involving intelligent and adaptable activities.

Cerebrospinal Function

The cerebrum is the organ which is the physical and neural instrument of activities which result in *conscious* sensory and motor behavior. Of all the complex activities which occur in the brain, only a minimum actually enters into consciousness; most functions are performed without our being aware of their existence.

We open our eyes, for example, and see a building. The light rays reflected by the building enter the eyes, fall upon the retina, and there activate the receptor cells. The stimulus inaugurates a nerve impulse which travels along the optic nerve to the visual center of the cortex, and the end result of the process is the perception of the building. It is this end product which becomes conscious to the mind; the intermediary process remains unconscious throughout. And if we desire to move the eyes, so as to see another object, we consciously and deliberately direct the movements of the eyes toward the object we wish to see. Somehow, then, we are able to stimulate the motor center which controls the muscles regulating the movement of the eyes. But how we are capable of selecting and stimulating the right cortical cells, and how the motor impulse travels from the cortex to the muscles, turning the eyes in a definite direction, we do not know; the process itself does not become conscious. A large amount of neural activity must take place in the brain between the start and finish of an apparently simple function, but we are unaware of its presence.

Consciousness is a state of the mind in which we are aware of our experiences, and these experiences may pertain to motor, sensory, or rational functions. Items of

conscious experience, for example, are the facts that I am walking, moving my arms, seeing the objects situated along the street, feeling the cold, thinking about the weather, desiring a ride in an automobile, etc., and I am presently aware of these items of experience. It is when I am wide awake and know what is happening to me and around me, that I am said to 'be conscious' or to 'have consciousness' of something.

Many functions of man are subject to conscious control; many are not subject to conscious control at all; and many are subject to conscious and unconscious control.

The higher functions, those of a *rational* character, are always subject to *conscious* control. To this category belong the formation of ideas and judgments, and the acts of reasoning and volition. How far these operations may be dependent on neural and cortical conditions, need not concern us at present. It is sufficient to state that they are under direct conscious control. Many *sensory* activities are also under direct or indirect conscious control. The sense organs, when exposed to a stimulus, will always react to the stimulus, irrespective of our wishes and desires; the open eye, for instance, cannot but respond to the stimulus of light, and the ear must hear the loud report of a gun discharged in its vicinity. We have, however, conscious control over the organs of sense to a certain

Fig. 13. Diagram of Cerebro-spinal Function.

(After Mercier). The figure shows the general paths of the sensory and motor nerves.

extent, in as much as we can direct these organs toward, or away from, definite stimuli. We can, for example, turn the eyes in this or that direction or close them entirely; we can sniff a flower or clamp the nose with our fingers; we can pinch our skin and feel the pain or refrain from such an action.

There are two kinds of muscles in the body, the smooth and the striped. The smooth are not under conscious control; the striped are. We are capable of intentionally flexing the arm or leg, turning the head, bending the body, manipulating an object, etc. All complex actions which require skill and are the result of 'learning' are consciously controlled actions. Such are walking, swimming, dancing, playing a musical instrument, writing, speaking, operating a machine, and so forth. Practice may make such activities semi-automatic, but they are always, in the last instance, under conscious control.

A large number of actions and functions in the human body are *not under conscious control*. Many of these never enter consciousness at all. Such actions and functions are usually controlled by the *brain stem* and *spinal cord*. If connecting fibers extend from the nerve centers of the stem and cord to the cortex of the cerebrum, we will, or at least may, become conscious of their presence; otherwise not. We are never conscious, for example, of the contraction of the iris of the eye under the stimulus of a bright light, nor are we aware of the modification of the curvature of the lens of the eye in focusing. On the other hand, if someone tickles us, we respond by shrinking away from the stimulation, but we are conscious of the process. Such actions are 'reflexes.'

Reflex Actions

A *reflex action*, or a *reflex*, is an act performed automatically and involuntarily, as a response to a stimulus, by a partial mechanism of the nervous system. The stimulus excites an afferent nerve; the impulse is transmitted along the afferent nerve fiber to a motor center, either by means of a synaptic connection, or by means of a single connecting fiber or a series of connecting fibers; the motor center is stimulated; the motor impulse travels along the efferent nerve fiber to a gland or muscle; upon reaching the gland or muscle, the end organ responds with the performance of its characteristic function. This sequence of neural activity is the so-called 'reflex arc.'

Reflexes are not learned; they are a *native endowment* of the organism's nervous system. Hence, they are inherited, and not the result of experience or practice or habit; they are localized in a definite set of nerves; they are not dependent on the action of the will, but on the influence of external stimuli. How little, at times, reflexes are dependent even on the life of the organism as a whole, can be seen in a disemboweled and decapitated frog; an electrical stimulus will induce a reflex action in the legs.

There are various *kinds* of reflexes. Some are *motor* reflexes, others *secretory*. 'Motor reflexes' have to do with contractions of the muscles. If I touch unknowingly a hot object with my hand, the hand jerks back automatically; if a bright light strikes the eyes, the pupils contract automatically. Here we have two distinct types of motor reflexes. The muscles of the hand and arm are striped

muscles and as such are under Conscious control, so that I can flex the arm and hand voluntarily; under the conditions just mentioned, however, the action is an involuntary reflex action. In the case of the pupillary light reflex, however, the muscles involved are smooth muscles and beyond the direct control of the will; the action of the pupils is always a reflex. 'Secretory reflexes' control glands and their secretions. When food is placed into the mouth, saliva is released; and when the food passes into the stomach, juices flow from the gastric glands. A few reflexes are *cortical*. Their centers lie in the cortex of the cerebrum; such are the reflex actions of coughing and sneezing. Most reflexes, however, as was stated above, are controlled by the *spinal cord* and the *brain stem*. A typical example of the former is the knee-jerk, effected by striking the tendon of the muscle just below the knee. The normal rhythm of the heart beat is an example of the latter. Besides the reflexes which induce a movement, there are *inhibitory reflexes* which stop a movement or hinder it from occurring. By relaxing the diaphragm one can often stop the hiccough reflexes, and by painfully pressing the upper lip against the teeth one can inhibit the tendency to sneeze. We have already noted how the sympathetic and parasympathetic sections of the autonomic nervous system counteract each other. Again, many reflexes are *regulative*, while others are *protective*. The entire autonomic system can be viewed as a vast system of motor and secretory reflexes, designed to regulate the processes of digestion, circulation, respiration, generation, and excretion; and many of its functions are also protective in character, as can be seen when germs and dangerous

elements enter the organism and are destroyed or eliminated. The closing of the eye lids when objects approach and the shedding of tears when a dust particle enters the eye, are instances of protective reflexes; so, too, are vomiting, coughing, withdrawal of the foot when stepping on a piece of glass, etc.

While reflexes are by nature automatic and involuntary, an *indirect conscious control* is possible, both in a *facilitating* and *inhibiting* manner. In many instances relaxing a muscle tends to interfere with the usual reflex; holding the leg out straight makes the knee-jerk

reflex almost impossible. Similarly, concentrated attention upon the expected reflex, e.g., the knee-jerk, inhibits the action. Contrariwise, conscious attention may reinforce or inhibit a reflex, as in coughing, sneezing, swallowing, vomiting, and so on; we can check or facilitate these reflexes to some degree according to our desire. We can also offset one type of reflex by counter-stimulation, as when we stop a spasm of sneezing by rubbing the nose or inhibit the winking reflex of the eyelids by holding the eyes wide open. Sometimes the forceful contraction of the muscles will prevent a reflex; thus, although normally the hand would reflexly withdraw upon contact with a hot object, we can force the hand to grasp the object firmly, thereby hindering the withdrawal reflex from operating.

Fig. 14. Reflex Action in the Spinal Cord.

Conditioned Reflexes

A conditioned reflex is the reflex response of a neural mechanism to a stimulus which has been substituted for the natural stimulus normally evoking this particular reflex action. An example will make this rather technical definition clearer.

The natural stimulus for the secretion of saliva is the presence of food in the mouth; the secretion of the saliva under such circumstances is a natural reflex of the neural mechanism in the presence of the food. This reflex, however, can also be evoked by a stimulus which, as such, bears no resemblance to food but is substituted for it. Some food is placed before a hungry dog. A bell is sounded for a few seconds, and then the food is given to the dog. After a short interval the process is repeated. This bell-and-food combination, after being made a dozen or two dozen times, has the peculiar effect that the saliva in the dog's mouth will begin to flow at the sound of the bell. Continuing the procedure for some days, it is observed that the saliva is secreted, even though no food is present, simply at the sound of the bell. Normally and naturally, the sound of a bell is not a stimulus for effecting the reflex action of salivation. Under the conditions given, however, it becomes a substitute stimulus for the presence of food in the mouth, so that the dog reacts as if he had taken food. The reflex of salivation is now 'conditioned' to the sound of the bell, and we have a 'conditioned reflex' in place of the natural or unconditioned reflex in the presence of food.

Pavlov began his experiments on the conditioned reflex around 1900, and since that time scores of psychologists have continued the work and extended the field of research among animals and men. A number of interesting facts were disclosed.

Conditioned reflexes can be acquired quite *naturally* through the *experience of life*. Through experience the animal soon learns to associate the sight of food with its taste. After a while, the sight alone is sufficient to elicit the salivation reflex. We say that the sight of food 'makes our mouth water.' Whether acquired through natural or artificial association, conditioned reflexes will readily sink into a state of *suspension or extinction*, if the natural stimulus, for which it is substituted, remains absent for any length of time. Thus, in the bell reflex mentioned above, if food is withheld from the dog through a number of experiments with the sounding bell, the amount of flowing saliva decreases gradually, until it reaches zero. In the animal's mind the bell stimulus is no longer associated with food, and the salivation response ceases. Then, if food is again given with the bell stimulus, the conditioned reflex receives a quick *restoration* to its full vigor. If the experiments of the conditioned reflex are omitted for a prolonged period, the animal simply reverts to the normal procedure of the natural stimulus, and the conditioned reflex is lost entirely. Such experiments show that the conditioned reflex is nothing more than a *temporary adjustment* to environmental circumstances; as the circumstances change, the conditioned reflexes change.

Almost *any* kind of stimulus can be substituted for the natural stimulus in conditioning a reflex. Various kinds of auditory, visual, and tactual stimuli have been used, and all have been successful. The main thing, of course, is that a combination or association must be established between the natural and the conditioning stimulus.

It is remarkable to what a degree a *differentiation* between stimuli of the same kind can be maintained by animals in their conditioned reflexes. Animals, for example, soon learn to differentiate between the sound of one bell and the sound of another, if the one stimulus is reinforced with food and the other not. If the reinforcement by food was delayed for a regular interval of time after the stimulus was given, say for a minute or so, the animal learned to adjust himself to the situation, so that the salivation reflex was delayed accordingly.

Conditioned reflexes have also been established in *human beings*. Experiments have been successfully performed on infants with a feeding bottle and a light or sound stimulus. As early as the third month of life, children distinguished between one sound and another. *S. P. Marquis* (1931) was successful in his attempts to bring about a conditioned reflex in newborn children after a few days, by using a buzzer signal just prior to feeding; at the sound of the buzzer the infants immediately commenced the oral movements of sucking. In *adults* the conditioned reflex is far more difficult to recognize, due to the conscious co-operation of the subject. Many experiments have been made, attempting to condition the reflexes of salivation, hand-withdrawal through shock, winking of the eyelid, and

knee-jerk. Quite a number of psychologists are convinced that conditioned eyelid and knee-jerk reflexes have been obtained. Others are not so sure. A reflex is almost always the response of a partial neural mechanism controlled by some lower motor center. The eyelid and knee-jerk responses due to conditioning, however, seem to lack the sharp, quick, spontaneous throw so characteristic of the natural reflex. Apparently, then, there is a certain amount of cortical participation in the new response; and, if that is the case, it would be more of an indication that the organism, through its higher centers, has learned to adjust itself to a new situation. In the case of human adults, therefore, it is still not clear whether true conditioned reflexes can be obtained. If consciousness and volition play a part in the final results of the response, it can hardly be a reflex action in the strict sense of the word.

Watson and the *behaviorists* generally look upon these and similar experiments as showing that all human behavior can be explained in terms of conditioned and unconditioned reflexes. According to them, a study of reflexes is the proper study of psychology; consciousness can be eliminated as a factor in human behavior, and introspection should be omitted as a legitimate method of investigation in studying mental phenomena. A conditioned reflex of the iris of the eye seemed particularly important to *Watson* as strengthening the foundation of behaviorism, because this would show that such a muscle, which is definitely not under voluntary control, could be positively conditioned in its reflex without the influence of conscious activity. *Cason* made experiments on this pupillary reflex

with a light-and-bell combination and found that the pupil contracted more under the stimulus of this combination than under the stimulus of light alone. However, as T. V. Moore points out, "a pupillary reaction, in spite of its involuntary character, is nevertheless indirectly subject to voluntary control. Every act of attention dilates the pupil. Every emotion does the same. Looking at a far point dilates it; looking at a near point or wrinkling the forehead contracts it. It is very likely that, as Hamel suggested, many of the experiments that were supposed to demonstrate conditioned pupillary reactions merely manifested the effect of apprehension on the size of the pupil."¹ And thus we see that conscious factors influenced the action of the pupil throughout the experiments, contrary to the supposition of Watson. Hence, consciousness cannot be eliminated as a factor in human behavior on the basis of conditioned reflexes.

Conscious factors are also present in animal experiments. It is difficult in many instances to distinguish between a true reflex controlled solely by an unconscious motor center and a sequence of behavior due to the conscious recognition of the necessity of an adjustment to new circumstances. After all, even a dog has reactions which manifest a conscious knowledge of his surroundings. If, then, he obtains food at the sound of a bell, he comes to expect this food at the sound, and this conscious expectation causes the saliva to flow; this reaction will continue until he realizes, after a change in the experiment, that food is no longer forthcoming at the sound of the bell, and then the flow of saliva progressively decreases and

eventually ceases altogether. The *apprehension and expectation* of food are conscious, psychic factors which must not be overlooked in these experiments. They rob the conditioned reflex of much of its mystery, and they show what little support behaviorists can derive for their theory from conditioned reflexes.

Our brief description of the nervous system and its functions in the human organism emphasizes the fact that man is a unit, a completely *integrated organism*. The complexity of the nervous system in its structural details and in its functions is beyond conception and description. Nevertheless, every single part, both in structure and function, is linked with every other part so intimately and effectively, that the result is a unified totality of marvelous compactness and activity.

Summary of Chapter III

The nervous system of man consists of two main subsystems: The cerebrospinal and the autonomic.

1. *The Spinal Cord.* It is a mass of neurons and nerve fibers, enclosed in the skeletal housing of the spine, and extends from about the base of the skull to the sacral region. The inside of the spinal cord consists of gray matter containing the nerve cells; the outside consists of bundles of nerve fibers. Two pairs of nerves emerge from both sides of the cord between each of the vertebrae. *Afferent* nerves emerge from the dorsal side, *efferent* nerves from the ventral side.

Connecting fibers unite these nerves among themselves and also with the brain.

2. *The Autonomic System.* It is that part of the peripheral nervous system regulating responses concerned especially with digestive, circulatory, respiratory, and reproductive activities. It is composed of two mutually antagonistic sections: the *sympathetic* (vegetative, visceral) and the *parasympathetic*. The latter section consists of two parts, the 'cranial' and the 'sacral.' The sympathetic section is more in the nature of an emergency' mechanism.

3. *The Brain Stem.* It is a prolongation of the spinal cord and is situated at the upper end of the cord. It comprises the *medulla oblongata* or bulb, the *pons*, the *cerebellum*, the *midbrain*, and the *thalamus*.

4. *The Cerebrum.* The cerebrum is the final enlargement of the spinal cord and brain stem. The *cortex* is the outer

surface and consists of gray matter, i.e., nerve cells; the inner portion consists of white matter, i.e., nerve fibers. The brain is furrowed by many fissures and convolutions. Three fissures are large: the median fissure, the fissure of Sylvius, and the fissure of Orlando. *Three types of nerve fibers* are found in the brain: sensory and motor fibers, association fibers, and commissural fibers. The cerebrum is the supreme organ of co-ordination and correlation for the organism.

5. *Localization of Function.* Certain areas of the brain are the localization centers for sensory and motor functions. The frontal lobe contains the motor areas. The somesthetic area lies behind the central fissure. The visual area is located in the occipital lobe. The auditory area lies in the temporal lobe. The olfactory and gustatory areas are situated centrally at the base of the brain. All these motor and sensory areas merge into association areas.

6. *Cerebrospinal Function.* The cerebrum is the organ which is the physical and neural instrument of activities which result in conscious sensory and motor behavior. Consciousness is a state of the mind in which we are aware of our experiences, and these experiences may refer to motor, sensory, or rational functions. Conscious control originates in the cerebrum. Many actions and functions are not under control, and these are usually controlled by the brain stem and the spinal cord.

7. *Reflex Actions.* A reflex action, or *reflex*, is an act performed automatically and involuntarily, as a response to a stimulus, by a partial neural mechanism of the nervous

system. Reflexes are an inherited native endowment of the organism's nervous system.

There are various *kinds* of reflexes: motor and secretory; inhibitory; regulative and protective; cortical and those controlled by the brain stem and spinal cord. Over many of the reflexes we have an *indirect* conscious control.

8. *The Conditioned Reflexes*. A conditioned reflex is the reflex response of a neural mechanism to a stimulus which has been substituted for the natural stimulus normally evoking this particular reflex action. Example: the salivary reflex evoked at the sound of a bell associated with food. Such reflexes can be suspended, extinguished, and restored. They are a *temporary adjustment* to environmental circumstances. Conditioned reflexes have been experimentally established in infants; in adults the success is doubtful, due to the conscious factors of adjustment.

Behaviorism hails these experiments as showing that all human behavior can be explained in terms of conditioned and unconditioned reflexes, thereby eliminating consciousness as a factor in human behavior. Their view is wrong, because both men and animals are conditioned in their reflexes through apprehension and expectation, and these are psychic factors.

Chapter 4

THE SOMESTHETIC SENSES

TO PSYCHOLOGY, THE BIOLOGICAL AND PHYSIOLOGICAL processes, even those of the nervous system, are of only secondary importance. Of primary importance are the *mental processes*. Man is a sentient organism. The term 'sentient' implies 'sensing,' and sensing has to do with sense cognition, sense knowledge. Sense cognition is followed by sense appetition, sense striving. These are the *two main types* of sense function: *sense cognition* and *sense appetition*. In these psychology is vitally interested, and they will be discussed in the following chapters.

Sense cognition is the first main phase of man's mental life which the psychologist and philosopher is called upon to investigate. Sense cognition is mediated through various bodily structures called the *receptors or sense organs*. Through these man obtains a knowledge of conditions present in his own body and in the world around him. The receptors are activated by stimuli which impinge on them and thereby convey information to the mind by means of the act of sensation.

Sensation and Perception

By a sense we understand a specialized mechanism or function by virtue of which an animal organism is receptive and responsive to a certain class of physical stimuli, resulting in *knowledge of some sort*. By *sensation* we understand a *conscious experience aroused by the stimulation of an organ of sense*. Certain receptor nerves terminate in specialized organic structures, like the ear, the eye, etc., peculiarly adapted to receive the excitation of a definite stimulus. The physical stimulus which arouses the sense organ to activity may be mechanical motion, heat, sound, light, electricity, or a chemical reaction. The stimulus itself, therefore, is some form of energy and resides in, and proceeds from, some object.

The *process of sensation* is as follows. On the *physical* level there is the stimulus. Aether vibrations, for example, affect the eye; air waves affect the ear. The stimulus now produces effects in the terminal elements of the receptor nerves, and these effects are *physiological and neurological*; a nerve impulse is set up and travels along the sensory nerves up to their respective center in the cortex of the brain. In the cortex the process ends on the *psychological or mental* level; man's consciousness is modified, so that he has a conscious experience of the stimulation of the organ of sense. He experiences, for example, color and sound in a conscious manner; in other words, he has a 'sensation' of color and sound. It is essential to the concept of 'sensation' that the final result be a *conscious* experience, a modification of consciousness. Not

all sensory impulses have this final result. In very many instances these impulses remain on the purely neurological level, traveling only as far as the spinal cord or brain stem, where they are shunted over to a motor center; the result, then, is a motor reflex which does not enter consciousness at all, and such a response is not a 'sensation.'

Depending on the attributes of the stimulus, a sensation also has various recognizable *attributes*. One of them is 'quality.' Color, for example, has a particular shade; sound has a particular tone. There is also 'intensity.' There is a more-or-less in the brilliance of color, in the loudness of a sound. Another attribute is 'duration.' A flash of lightning is not seen as long as the light of the desk lamp while reading; the report of a pistol is heard for a shorter period of time than the noonday whistle of a near-by factory. Quality, intensity, and duration are common attributes of all sensations. Primarily, these are the attributes of the stimuli; however, in as much as sensations are directly dependent on the stimuli, they are also the attributes of the sensations themselves.

The student must distinguish well between *sensation* and *perception*. In common parlance the distinction is seldom made, but modern psychologists are very emphatic on this point. 'Sensation' has just been defined. By *perception* we understand *the cognizing of the object which produces the sensation*. Sensation has reference solely to the stimulus; perception has reference always to the object furnishing the stimulus. In sensation I become conscious of the stimulation of a sense organ purely as such; in perception I become conscious of the object presently and actively

engaged in the stimulation of a sense organ. Consider the following situation. There is a green blotter on my desk, and on the blotter is a sheet of white paper. In the dark I see nothing; but as soon as I turn on the light, I begin to see. Just what do I see? From the standpoint of a 'sensation,' I am conscious of seeing a patch of 'white' and a patch of 'green'; the stimulus of light has produced in me the conscious experience of 'white' and 'green.' From the standpoint of 'perception' I see 'an oblong sheet of white paper against the background of a green blotter.' In this process of perception, therefore, I refer the sensation 'white' and 'green' to the 'paper' and the 'blotter' and include also the 'relation' of the one to the other. The mere fact of seeing 'white' and 'green' does not tell me at all that they refer to 'paper' and a 'blotter'; that knowledge was acquired before through some other process of knowing, and so I now refer the 'white' and 'green' to these known objects in the present act of sight. Another illustration. Someone holds an object to my nose, requesting me to smell, and asks "What do you smell ?" If I answer, "Something fragrant," I declare my sensation; but if I answer "A rose," I declare my perception. A final illustration: If through my hearing I am aware 'of sounds following one another,' I have merely a sensation; if, on hearing these same sounds, I am aware of 'hearing a robin sing,' I connect the sensation with the object furnishing the stimulus and have the far more complex perception.

Perceptions always involve past sensations of the same and of different kinds and combine them in the *recognition of the object* which caused them. The stimuli come from

objects and thereby convey to the mind items of information regarding the objects themselves. It is the inherent purpose of stimuli to acquaint us with these objects, whether these objects are *within* our own organism or are *external* to our body. Hence, we seldom stop at the primitive experience of the sensation itself, but immediately pass on to the experience of the object causing the sensation. Thus, we rarely speak of merely 'an ache' but of a stomach ache,' and we are practically never conscious only of a patch of 'blue' but rather of a 'bluebird.' In everyday life, therefore, we occupy ourselves with perceptions, not with pure sensations. The ordinary man is not interested in sensations as such; since, however, perceptions are elaborations of sensations and sensations are the underlying units of perception, the research psychologist is interested in the fundamental distinction between the two kinds of mental experiences. The student should know the distinction.

The Senses

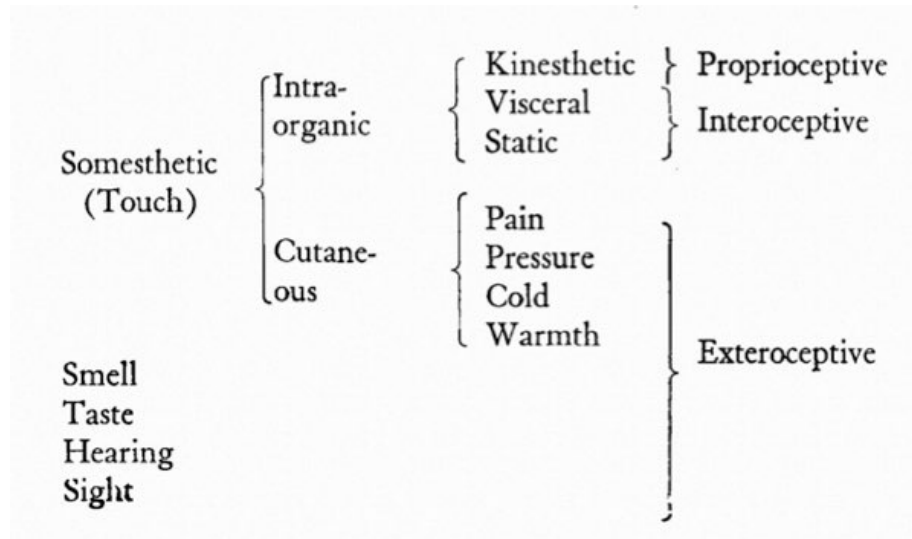

Man possesses a number of senses. A classification can be made according to a variety of standpoints. A classification, based on common experience and in vogue for over 2000 years, is the division of the senses into *external* and *internal*. The external' senses were subdivided into sight, hearing, taste, smell, and touch; the 'internal' senses, into the central sense, imagination, sense memory, and instinct.

Modern psychology accepts the external senses as enumerated, but insists that the sense of 'touch' really is composed of a number of distinct senses, namely, the sense

of warmth, of cold, of pressure, of pain, the kinesthetic sense, the visceral sense, and the static sense. Of these, only the sense of pressure should properly be designated the sense of 'touch.' As a matter of mere convenience and methodology, these senses are often grouped together under special headings; there is, however, no uniform practice among psychologists in this regard. Usually, this entire 'touch' group is referred to as the *somesthetic* or *body senses*, or still more simply as the somesthetic or body sense. The senses of warmth and cold are often spoken of as the 'temperature sense.' Again, the senses of pressure, pain, and temperature are called the 'cutaneous' or 'skin senses, while the visceral, kinesthetic, and static senses are termed the intra-organic senses.

Another classification of the external senses is based on the *origin of the stimulus*, consideration being given to the *kind of objects* of which they convey information. Viewed from this standpoint, psychologists speak of *exteroceptive, interoceptive, and proprioceptive* senses. An 'exteroceptive sense' is one which is activated by stimuli originating outside the organism. The senses which belong to this class are sight, hearing, taste, smell, the senses of warmth, cold, pressure, and pain; their stimuli originate from objects which lie outside the organism itself. An 'interoceptive' sense is one which is activated by stimuli originating within the viscera and within the vestibule of the internal ear. The visceral and static senses belong to this class. The 'proprioceptive' sense is the sense which is activated by stimuli originating within the organism by movement or tension in its own tissues. This is the kinesthetic sense.

For the purpose of correlation and clarification, the different classes of senses can be ordered as follows:

External Senses

Internal Senses

Central or synthetic sense

Imagination

Sensory memory

Instinct

The main division of the senses into 'external' and 'internal' is named this way in deference to history, because these are the designations handed down through the centuries. The terms, however, must not be taken too literally. In particular, the term 'external' is to some extent a misnomer. The intra-organic senses are not really 'external' or 'exteroceptive,' because their stimuli originate within the organism itself; for this reason they should, perhaps, be

classified as 'internal.' Nevertheless, we retain the nomenclature for want of more appropriate terms.

After these preliminary definitions and classifications, it will now be necessary to study the senses and their functions more in detail. Since the intellect depends, as will be shown later, on the internal senses for the preparation of its material and the internal senses depend on the external senses for the preparation of their data, the logical procedure will be to begin with the external senses. Among the external senses the element of cognition is expressed in unequal measure — most in sight and hearing, less in taste and smell, least in the somesthetic senses. Beginning with the lowest and progressing upward to the highest, the somesthetic senses will be considered first in the order of treatment. They are the subject matter of this chapter.

The Cutaneous or Skin Senses

A number of the somesthetic or body senses are located in the *skin region*. The skin is the protective covering of the human body and is composed of two main layers: the outer skin or *epidermis* and, underneath the epidermis, the *dermis* or *corium*. These layers rest on a tissue of subcutaneous fat. This region is the seat of the sense organs grouped together under the term 'cutaneous senses,' namely, the senses of *pressure, pain, warmth, and cold*.

Experimental research in psychological laboratories soon brought out the fact that stimuli applied to the skin did not evoke the same response over all areas. It also brought

out the very important fact that the different responses represented sensations of totally different types, so that a number of senses had to be accepted instead of the one general sense of 'touch.' It is now generally recognized that the sensations of pressure, pain, warmth, and cold originate in structurally different parts or organs. Just what these organs were, remained obscure for a long time; and even to this day physiologists and psychologists are still much in doubt as to the exact nature of the organs and their function.

Fig. 15. Cross Section of the Skin.
Various organs of the cutaneous senses are shown.

The skin contains various types of nerve endings associated with the cutaneous sensations. Some of these have a distinctive anatomical structure. There are capsules or sheaths of fatty tissue, richly supplied with minute blood

vessels and a network of nerve endings. Prominent among these capsulated organs are the *Paenian and Meissner corpuscles, the Krause bulbs, and the end organs or Ruffini*. The *hair follicles* also play their part in cutaneous sensation. The root of the hair is encircled by numerous nerve endings. Most frequently present throughout the skin area of the body are *free nerve endings*. They are the terminal branches of nerves and have no specific organic structures as receptor organs; they themselves receive the stimuli and transmit the sensory impulse. These nerves are distributed quite freely in the skin, but the distribution is rather uneven for the individual types. It is the presence or absence of one or the other of these types of nerve endings in definite skin areas which has enabled experimenters to connect them with certain types of sensations. The *method* commonly employed is the use of a stylus or bristle, applied point by point to a localized area of skin surface. This punctiform method of investigation brought out the startling fact that the skin is not uniformly sensitive, but consists of *sensitive spots*. These spots differ in the character of their sensitivity, so that we are able to distinguish pressure spots, warmth spots, cold spots, and pain spots.

The Sense of Pressure

During the years from 1883 to 1885 three physiologists, Donaldson, Blix, and Goldscheider, proved by experimental evidence that the sensations of pressure, warmth, and cold resided in spots or points of the skin. A decade later (1894)

von Frey furnished the proof that the pressure and pain senses were distinct and were localized in different spots. Beginning with the fact that light pressure or contact does not elicit the sensation of pain, while strong pressure does, he drew the conclusion that the phenomenon could be explained only on the grounds that pressure and pain were separate senses and responded to different stimuli. He thereupon engaged in a series of systematic experiments to prove his hypothesis. He used as his investigating instruments straight hairs, graduated according to thickness and strength, and measured their pressure on the skin by a delicate balance scale. The standard used was the gram per square millimeter. His computations showed that pressure and pain have different thresholds, the threshold for pressure being the lower and that for pain the higher. He also discovered that some areas of the skin are sensitive to pressure only, while others are sensitive to pain only. He thus proved his hypothesis.

Experiments show that a considerable *variation* exists in the sensitivity of the skin toward pressure. The tip of the tongue and the tips of the fingers are very sensitive; the abdomen and the back of the forearm possess a much reduced sensitivity; the thickened skin of the soles of the feet has very little sensitivity. Much depends on the thickness of the skin and the number of pressure or touch spots in a particular region. This number differs appreciably in different parts of the body. It is estimated that there are approximately 5 to 10 pressure or touch spots per square centimeter, as an average, on the arm or leg, 30 on the chest, 50 on the forehead, 100 on the lips and

fingertips, and 120 on the ball of the thumb. A few restricted areas seem to lack pressure spots almost entirely; such is the case with the mucous membrane lining the inner surface of the eyelids, which is extremely sensitive to pain but scarcely registers pressure at all. On the hairy portions of the body, the pressure or touch spots are located to windward of each hair, that is to say, close over the hair follicle.

The *stimulus* for pressure sensation is anything which, upon contact, alters the even surface of the skin. Pushing against the skin, or lifting it, or bending it aside, is a stimulus exciting the pressure sense. Any such modification of the surface must affect adjacent and underlying tissues and thereby stimulate the pressure receptors.

It is certain that the hair follicles serve as the receptors of pressure in those parts of the body where hair is present. However, not all parts are covered with hair, though they are sensitive to pressure; for example, the lips, the tongue, the palm of the hand. It is fairly certain that the *Meissner* corpuscles and perhaps also the *free nerve endings* serve as pressure organs in these and other portions of the skin.

Some interesting *phenomena* are associated with the experience of pressure. In some instances, depending on the region stimulated, pressure is experienced as a mere 'contact,' in others more distinctly as 'pressure,' and again in others as a 'tickle.' Another phenomenon is that of 'adaptation.' When a stimulus is applied steadily to the pressure organs, they adapt themselves to the situation, and the sensation of pressure gradually fades and then vanishes. When the stimulus is changed, the sensation

reappears. Such experiences are common. After a brief period of time, we no longer feel the clothes on our body, or the hat on our head, or the shoe on our foot, even though they fit tightly and press with some force against the skin; we become insensitive to the pen or cigarette held quietly between the fingers; we do not notice the pressure of the chair on which we are sitting or of the bed on which we are lying, until we change our posture. The sensation of pressure and touch is diminished or ceases temporarily.

The Sense of Pain

Of all the cutaneous sensations, that of pain is the one most unpleasant and most dreaded. More than any other, the pain sense serves as a protection safeguarding the integrity of the organism against injurious agencies. The presence of pain is always a warning signal.

The *stimulus* producing the sensation of pain is some object or condition which injures or nearly injures nerve tissue. The pain *receptors* are undoubtedly the 'free nerve endings.' They are known to be present wherever pain is felt. These free-branching nerve endings are distributed over the entire surface of the body, and pain can be elicited everywhere. In the center of the cornea of the eye the only sensation present is that of pain, and in this area we find only free nerve endings. From these facts of distribution physiologists conclude that the free nerve ends are the true pain receptors. Notwithstanding its great physiological importance, the pain sense is the most primitive of all,

because it lacks anything resembling an 'organ' proper, consisting merely of the terminal branches of nerves.

This very lack of structural specialization, however, makes the pain sense peculiarly adapted to report injuries, because even a pin prick or slight scratch of the epidermis will immediately attack the tissue of the nerve endings themselves.

As for the *distribution* of the pain spots, they are more numerous than those of the other cutaneous senses. This distribution is, like that of the other sensitive spots, uneven in the different portions of the body; much depends, too, on the constitution of the individual. In general, though, the respective areas of the skin are practically the same in all human beings, so that it is possible to give a statistical average of the number of pain spots present in a particular region of the skin. Taking as a standard the number of spots per square centimeter, it has been estimated that there are about 45 pain spots on the tip of the nose, 60 on the ball of the thumb, and close to 200 on the back of the hand, the chest, and the inner forearm. Kiesow states that a small patch of membrane, situated opposite the second molar tooth on the inner surface of the cheek, is entirely devoid of pain spots.

One of the *phenomena* of pain sensation is its 'latent period.' It takes more time to arouse this sensation than it does in the case of the other cutaneous senses, and it also takes more time for the effect to disappear. The pain sense is relatively slow in its operation. The pressure sense is relatively fast, and this difference in reaction time is another indication that these senses are distinct. The pain

sense possesses a certain amount of 'adaptation' to the steady application of a stimulus, demanding intervals for recovery to full efficiency. From a psychological standpoint, the 'quality' of pain varies from a sharp sting to a dull ache. Pain originating from the internal organs of the body is always pathological in character.

Contrary to what might be expected, there are no sensitive spots for pleasure, although pleasure is usually considered to be the counterpart of pain as much as cold is the counterpart of warmth. Evidently, then, pleasure is a condition of the organism totally different from that of pain. Pleasure will be considered in a later chapter.

The Temperature Sense

Physiologists and psychologists often speak of the 'temperature sense' in the singular, as if there were but a single sense for warmth and cold; then again, they often refer to the 'sense of warmth' and the 'sense of cold,' as if they were two separate senses. Many, perhaps most, of these scientists favor the two-sense view, but there is always a note of uncertainty in their expression.

Up to date, the *experimental evidence* is neither clear nor conclusive, notwithstanding the great amount of research work done in the laboratories. It has been found that the cold spots of the skin far outnumber the warmth spots; and it has also been discovered that there are regions where cold spots are present while warmth spots are absent, and vice versa. There is also good evidence in support of the view that the cold receptors are close to the

skin surface, while the warmth receptors lie deeper; when the skin is cocaineized, the cold sensation disappears first and the warmth sensation later. This evidence argues for the two-sense view.

Offsetting this evidence is the fact that these spots do not seem to be stable; the location and the number of spots shift about to a certain extent from experiment to experiment with the same subject. Besides, when the stimulus is increased, namely, by using a somewhat warmer or colder stimulus than was used before, the number of sensitive spots is also increased; this fact does not seem to conform with the theory of fixed receptors of warmth and cold with a punctate form of distribution. It may be, of course, that some spots are more sensitive than others, and that an increase of the stimulus produces its effect over a wider area with a corresponding involvement of more spots.

If it were possible to identify definitely two distinct types of receptor organs for the sensations of cold and warmth, the problem would be solved. Investigators associate the sensation of cold with the *end bulbs of Krause* and the sensation of warmth with the *end organs of Ruffini*. There is some experimental evidence which points to these structures as being the organs of cold and warmth, but this evidence is also not conclusive. Von Frey had already observed that the conjunctiva of the eye is very sensitive to cold, and this area abounds with the Krause bulbs. Strughold and Karbe, using a very ingenious method of mapping the cold spots, confirmed the findings of von Frey; every cold spot of the conjunctiva was found to correspond to a Krause bulb located at the spot. There is thus little

doubt that the Krause end bulbs are cold receptors or at least are associated with them. The problem, however, is still left unsolved. Cold spots are very numerous in the skin and are freely distributed over the entire surface of the body; and yet, despite repeated efforts, investigators have failed to discover the presence of these end bulbs in the skin where the cold spots are located.

Another phenomenon which seems to militate against the two-sense theory is the fact that very intense stimulation of the temperature spots is sensed as a 'burning.' It is commonly known that contact with an extremely cold object is experienced as a 'burning' sensation and not as cold. If the cold and warmth receptors were specifically distinct as senses, this fact is, to say the least, disturbing.

Due to these apparently conflicting facts, some scientists look for the true stimulus source of cold and warmth in the *blood vessels*. A 'dilation' of the vessels would be the stimulus for the sensation of warmth, a 'constriction' of the vessels for that of cold, and a 'spastic constriction' the stimulus of the burning sensation which is aroused by extreme excitation. There is, however, little positive evidence for this theory.

And so there is still uncertainty whether we have a single common temperature sense or a distinct sense for warmth and another for cold. Future investigation may settle the question. Leaving this matter aside, we will now give our attention to factual information concerning the sensations of warmth and cold.

The *distribution* of the cold and warmth spots is rather variable. The cold spots far outnumber the warmth spots, considered as a whole, although in some restricted areas the warmth spots predominate. Striking an average from the results obtained by a number of investigators, von Stramlik¹ gives the following averages per square centimeter of skin surface. Cold spots: forehead, 8; tip of nose, 13; chest, 9; volar side of forearm, 6; back of hand, 7. Warmth spots: forehead, 6; tip of nose, 1.0; chest, .3; volar side of forearm, .4; back of hand, .5; Sommer estimated that the entire body surface contains about 250,000 cold spots and 30,000 warmth spots, with an average of 12—13 cold spots and 1—2 warmth spots per square centimeter.

Warmth and cold have no absolute values, but are relative in character. Whether a *thermal stimulus* will or will not arouse the sensations of warmth and (or) cold, depends upon the temperature of the skin to which it is applied. If the temperature of the stimulus is higher than that of the skin, it is experienced as 'warmth'; if the temperature of the stimulus is lower, it is experienced as 'cold'; and if the temperature of the stimulus is the same as that of the skin, neither warmth nor cold is experienced. Warmth and cold are simply modalities which are relative to the temperature of an organism. The skin temperature is termed *physiological zero*, because that is the temperature to which the organism is 'indifferent.' Various portions of the skin may have different physiological zeros, in as much as one portion may be warmer or colder than another. On a very cold day the physiological zero of the exposed parts, such as the hands and face, will be lowered with respect to

the covered parts; on a very hot day, or when exposed to a fire, it will be raised. It then happens that the same thermal stimulus will be experienced as warm and cold when applied to different parts of the skin.

One of the phenomena connected with the temperature sense is that of *paradoxical cold* and *paradoxical warmth*. Of the two, paradoxical cold is obtained more frequently. Paradoxical cold results under a special set of conditions when a hot stimulus is applied to the skin and there arouses, not a sensation of warmth, but a sensation of cold instead. If a temperature of 45° C. is applied for a short time to the front of the forearm and then a contact is made with a stimulus of 48° C., a sensation of cold will be experienced. The explanation given is, that the warmth receptors have adapted themselves to the temperature of 45° C. and do not respond immediately to the increased temperature of the second stimulus; the cold receptors, however, are able to respond to this stimulus by a cold sensation, since they have not been weakened by the temperature stimulus of 45° C. and can respond in full force.

The *reaction time* for the sensations of cold and warmth is different. When a cold spot is stimulated, the sensation in all its intensity is experienced at once, but the sensation of warmth reaches its full intensity only gradually. This difference in reaction time probably receives its explanation in the fact (if it is a fact) that the warmth receptors are situated in the deeper tissues.

The sensation of *heat* (not mere warmth) is peculiar. The stimulation of warmth spots alone will never arouse the

sensation of heat. Intense stimulation will produce the sensation of warmth or pain (pain will ensue, because of the injury to nerve tissue), but not 'heat.' In order that 'heat' be experienced, it is necessary that both warmth and cold spots be present in the stimulated area. It is therefore assumed that heat is not a simple sensation, but a blended sensation of warmth and cold resulting from the simultaneous stimulation of adjacent warmth and cold spots. That it is a blended sensation is born out by the heat-grill experiment. The grill consists of small tubes placed in parallel a few millimeters apart, warm and cold water alternating in the parallel tubes, so that warm stimuli affect warmth spots and cold stimuli affect cold spots in the same general area. Although no real heat is applied in this experiment, the subject, by placing his hand or forearm on the grill, soon experiences 'heat' without pain. Psychologists call this 'synthetic' heat,' in contrast to real heat. When 'burning heat' is experienced, due to the application of an extremely hot or cold stimulus, pain receptors are also involved in the stimulus pattern.

Adaptation to stimuli is noticeable to a marked degree in the temperature sense. Under steady stimulation of moderate warmth or cold the skin adapts itself by a corresponding shift of the physiological zero. The surface temperature of the exposed parts of the body is usually between 30-32° C. (86-90° F.). If the left hand is placed in a jar of water with a temperature of 20° C. and the right hand in water of 40° C., the left hand will at first have the sensation of cold and the right hand of warmth; soon, however, both hands will have no sensation of cold or

warmth at all, because of adaptation to the two temperatures. On placing both hands then in a jar of water with a temperature of 30° C., the sensation for the left hand will be that of warmth and for the right that of cold: the same temperature appears cold and warm at the same time. The *limit of adaptation*, according to experimenters, ranges from about 16° C. to about 40-42° C. As a rule, adaptation is impossible below this minimum and above this maximum temperature; in other words, in most individuals, anything below 16° C. will always be experienced as cold and anything above 42° C. as warm, without a physiological zero being established.

This description concludes our examination of the cutaneous senses of pressure, pain, cold, and warmth. They are *exteroceptive* senses. Next in line among the somesthetic senses are the *intraorganic senses*.

The Visceral Senses

There are two main types of intraorganic senses, the interoceptive and the proprioceptive. Two kinds of senses are *interoceptive*: the visceral senses and the *static* sense. They are called 'interoceptive,' because in their case the stimulus is not furnished by objects outside the organism but by organs lying far beneath the skin in the *interior* of the body. Through them we become aware of sensations aroused by stimuli originating within the body itself. One set of stimuli has its source in the *viscera*, or, generally speaking, in the vegetative organs. Sensations arising from this set of stimuli acquaint us with the condition of our

internal organs. The senses mediating these sensations are termed the *visceral senses*. The other set of stimuli has its source in the inner ear. Sensations produced by this set make us conscious of the equilibrium present or absent in the position of our body; hence the term static sense. The visceral senses will be described first.

Perhaps the best way to treat the visceral senses is to describe the *various kinds of visceral sensations*. 'Visceral sensations' are those which are aroused through changes of the inner organs and have the purpose of acquainting us with the condition of our organism, particularly with the *disturbed functions of vegetative life*. These sensations are many and diverse.

Some pertain to the musculature. Among these may be mentioned the sensation of fatigue, of freshness, of strength, of weakness, of relief after bodily strain in work, etc.

Others pertain to the nutrition system. The sensations of hunger and thirst stand out prominently. *Hunger* comes from the need of solid food. It is localized in the mouth, the throat, and the stomach. It manifests itself as a sort of dull pressure in the region of the stomach, but it may eventually turn into a painful sensation. *Thirst* is a sensation expressing the need of fluids in the system and is localized in the soft palate. It is assumed that a deficiency of lymph causes the membrane of the palate to shrink, thereby causing a stimulation of touch corpuscles present in that region. *Nausea* is a pronounced disgust or loathing of food, often accompanied by the vomiting reflex; nausea is primarily localized in the throat.

Functional disturbances of the *digestive* tract manifest themselves in a variety of sensations, ranging all the way from the dull discomfort of a general malaise to the sharp, spastic pains of griping, etc. These sensations may be only generally localized in the abdomen or sharply localized in a definite area, depending on the affected organs and the degree of functional disturbance. When the organs perform their operations in a normal manner, we are unconscious of their presence.

Then, there are sensations arising in connection with the *respiratory* and *circulatory* systems. In violent exertion, we experience a Constriction of the chest; in asthmatic conditions, a sensation of suffocation; after shock or a fast run, a painful contraction of the heart, etc. Associated with the functioning of the circulatory sensations are shuddering, itch, 'goose flesh,' and tingling, etc.; these are blended sensations in which pressure, pain, and other sensations are mixed.

In general, it should be noted that the organic sensations convey *little cognitive information*, but involve strong feelings. Their purpose is the *protection* of the organism in its vital functions, demanding imperatively our attention so as to obtain a correction of functional or organic disorders. Hence, pressure, pain, warmth (fever), and cold (chills) play such an important part in the pattern of visceral sensations.

For a long time the opinion was prevalent that the internal organs are insensitive to external stimuli. This belief was based on the statement of surgeons. Even severe handling of the internal organs do not seem to produce any definite sensory reactions. However, experimentation under

favorable conditions shows that sensibility to chemical, thermal, mechanical, and electrical stimuli is present, and positive reactions result in practically all regions, if not to all stimuli, then at least to some. Exact localization is usually difficult to determine, since the vegetative organs as a whole have only a very indirect connection with the conscious centers of the cortex.

It is very *doubtful* whether any *special senses* participate in visceral sensations. No unusual anatomic structures have been discovered so far which might be construed as being new sensory organs, different from those already described in cutaneous reactions. Apparently, the receptors of pressure, pain, cold, and warmth combine in the viscera in various patterns and thus give rise to different visceral sensations.

The *static sense* is an intra-organic sense, the end organs of which lie in the internal ear and are stimulated by the pull of gravity and by head movements. It is also termed the 'labyrinthine,' 'vestibular,' and 'equilibrium' sense. The name 'static' or 'equilibrium' sense is used, because this sense acquaints us with the position of our body in rest and motion. The name 'labyrinthine' or 'vestibular' sense is used, because the 'labyrinth' and 'vestibule' refer to the internal ear where this sense is located.

The *organ* of the static sense consists of a number of specialized parts: *the semicircular canals, ampullae, utricle, and saccule*. The semicircular canals are filled with a liquid and stand roughly in the directions of three planes placed at right angles to one another, like the floor and the two joined walls of a room. At the base of each canal the

structure bulges out into a vase-like formation, the ampulla. A vestibule or chamber unites the canals in the region of the ampullae. The ampullae have cells with hair-like endings which are mechanically stimulated by the pressure of the liquid, or endolymph, present in the canals and ampullae. The utricle and saccule contain otoliths which are minute crystals of carbonate of lime. The entire structure is frequently called the 'labyrinth.'

The *functions* of these parts are presumed to be as follows. The *semicircular canals* are directly concerned with *rotary movements of the head* and indirectly thereby also with rotary movements of the body, provided the head and body act as a unit and have the same

movement without changing their position relative to each other. No matter in what plane the head rotates, the liquid of one or the other of the canals will be affected by the movement. The liquid, or endolymph, presses against the cell hairtips of the ampulla, bending them out of their normal position. These hairtips stimulate the receptor cells in which they are rooted, and these receptor cells respond with a nerve impulse which results in the sensation of rotary movement. As the rotary movement continues, the endolymph adjusts itself, and the hairtips return to their normal position, the stimulation ceasing. As for the functions of the *otoliths*, it is assumed that an inclination of the head in any direction causes these little stony particles

Fig. 16. Vestibular Organ of the Static Sense.

to sag and thereby bend the hairs in which they are embedded, producing a stimulation of the receptor cells. This stimulation continues as long as the head (and body) deviates from its normal *position*. The static sense, therefore, is a sense of positional equilibrium and orientation in head movements.

The position of the vestibular organ in the interior of the head makes experimental *verification* of these assumptions very difficult. Whatever evidence there is, confirms the assumptions. Pressure on the canals, anesthetization, inflammation, resection, partial or total destruction of the labyrinth, etc., show effects of interference with the equilibrium of the bodily members just as happens in change of movement and position. An example. When normal people rotate around the axis of their body and come to a stop, they experience the illusion of rotation for some time and have the feeling of dizziness. Those deaf-mutes, however, whose vestibular organ is destroyed, experience no dizziness after rotary movement and proceed to walk without the staggering gait observed in normal people; on the other hand, it is claimed that they lack the sense of orientation when immersed under water with closed eyes. Ordinarily, like other people, deaf-mutes are able to know and maintain their body positions through visual cues, body pressure from surrounding objects (e.g., the pressure of the earth against their feet when standing, or the pressure of the bed against their body when lying down), and gravitational pull. When these factors are more or less neutralized (as through immersion under water with closed eyes), their sense of positional equilibrium is lacking,

due to the absence of the vestibular organ. When the otoliths of a fish have been removed, it also lacks body equilibrium and is indifferent to position.

Impulses from the vestibular organ are transmitted to reflex centers of the brain stem and cerebellum, producing compensatory adjustments of the head and limbs and oscillatory movements of the eyes (nystagmus). 'Sea-sickness,' 'train-sickness,' 'car-sickness,' 'elevator-sickness,' and 'plane-sickness' are visceral reflex reactions sometimes originating from vestibular impulses. A considerable amount of *adaptation* is possible, as can be seen in the case of acrobats, whirling dancers, and aviators; they adjust themselves quickly after violent movements.

The Kinesthetic Sense

The last of the somesthetic senses is the *kinesthetic sense*. It mediates sensations of the *position* and of the active and passive *movements* of the *bodily members* in relation to one another. By 'active' movements are meant movements of our limbs which we execute voluntarily, through our own effort; by passive movements, those movements of our limbs executed through someone else, as when someone lifts our hand without active participation or resistance on our part.

A number of different *sensations* must be considered with reference to the kinesthetic sense. There are sensations with regard to the *position* of the members in *bodily posture*. We know, for example, even without looking, whether the arm is raised or lowered, whether our knees are flexed or straight, whether our fingers are clenched or

relaxed, etc. Again, we experience sensations acquainting us with the *movements* of our limbs. In passive movements these sensations are localized apparently in the joints; in active movements they are localized more in the tensed muscles. Then, we have the sensation of *resistance*. In pushing against a solid wall, we not only experience touch and pressure on the surface of the hand, but also resistance in the joints of the hand, elbow, and shoulder. Finally, there is the sensation of *weight*, localized in the joints, tendons, and muscles.

Sensations seem necessary for *voluntary* movements. Such movements are apparently impossible whenever sensations are excluded. In the cases of organic loss of sensibility, where no sensory impulses reach the cortex of the cerebrum from the limbs themselves, patients cannot voluntarily move these limbs, even though the motor centers and nerves be intact, nor are they conscious of any passive movements executed by others. But if they can see their limbs, they can perform voluntary movements without any difficulty, provided the motor centers and nerves be intact. In normal persons such movements are possible even with the eyes closed. These facts indicate that in normal, voluntary movements sensory impulses must travel from the muscles to the brain in order that such movements can be executed.

There is uncertainty in the minds of physiologists as to the particular *organ* which serves as the reception for kinesthetic stimuli. For a long time the *muscles* were considered to be the anatomical substrate for this sense, and accordingly it was named the 'muscle sense.' This view,

at least in this exclusive and simple form, had to be abandoned. In some pathological cases, where the muscles had degenerated and were totally inactive, the patients preserved the sensations of posture and resistance and recognized the passive movements of their limbs. The muscle, as such, therefore, is not the organ of the kinesthetic sense. Others sought to reduce the kinesthetic sensations to *skin pressure* or to the *feeling of innervation* of the muscles. It was found, however, that the pressure sense could be destroyed, while the sensations of active and passive movement continued. The feeling of the innervation of the muscles in movements is, no doubt, an important factor in the normal sensing of voluntary movements, but it can hardly be the true kinesthetic sense. Some patients, after an accident, were able to execute movements correctly as ordered, but they did not know, unless they looked, whether they had actually made the movements. They innervated their muscles and were aware of the feeling of innervation, yet they were unaware of the movements themselves.

Perhaps the fundamental form of sensation concerning the position and movement of our members is that of *muscular tension*. Pressure, touch, and the feeling of innervation no doubt play an important part in normal kinesthetic sensation, but there are two structures which seem to have a special significance in this connection: *the muscle spindles and tile end organs of Golgi*.

The *muscle spindle* is a capsulated bundle of muscle fibers (Weissmann fascicle) located in a muscle close to where the fibers of this muscle pass over into tendinous

fibers. The capsule is connected with the tissue of the muscle by an outer layer of connective tissue. Besides the motor nerves which terminate in motor plates on the muscle fibers, a set of sensory nerves enter the spindle and coil around the muscle fibers of the spindle. Any contraction of the ordinary muscle is thus bound to stimulate these nerves of the capsulated muscle spindle and transmit a sensory impulse. The tendons possess similar spindle-shaped structures, the *end organs of Golgi*. Their function must be the same as those of the muscle spindles. There are, then, two special structures in the muscles and tendons situated where they are capable of localizing sensations of position, movement, resistance, etc. The neuro-muscular end organs of the muscle spindles register muscular contraction and thereby enable us to experience the position of our members. The neuro-tendinous end organs of Golgi register intense muscular effort, acquainting us with the resistance offered by objects.

Besides these two special structures, numerous *corpuscles of Ruffini* are located around the tendons, the capsules of the joints, and the periosteum (membrane of connective tissue investing the bones), while *corpuscles of Pacini* are present around the joints. The former probably react to tension, and the latter to pressure. It would therefore seem that they also play a part in the general pattern of kinesthetic sensations as a whole, though a minor one, whereas the muscle spindles and the tendon spindles have the major roles.

The kinesthetic receptors are termed *proprioceptive*, because they are activated by stimuli produced within the

organism by movement or tension in its own tissues.

Kinesthetic sensations are very important for the performance of properly coordinated bodily movements. Impairment brings on serious disturbances. Ataxia, or the inability to coordinate voluntary movements, is an abnormal condition due to impairment of kinesthetic function.

All the somesthetic senses — pressure, pain, temperature, visceral, static, and kinesthetic — have as their primary purpose the *protection and well-being of the organism as a whole*. None of these senses acts as an isolated sensory unit. Their functions are interrelated and interdependent. They serve the organism in performing the normal activities of its vital organs and in safeguarding its integrity against injurious influences from within and from without; at the same time they convey much information about the environment in which man lives. The somesthetic senses show that man is an *integral organism*.

Summary of Chapter IV

Sense cognition is mediated through various bodily structures called the receptors or *sense organs*.

1. *Sensation and Perception*. A *sense* is a specialized mechanism or function by virtue of which an animal organism is receptive and responsive to a certain class of physical stimuli, resulting in knowledge of some sort. *Sensation* is a conscious experience aroused by the stimulation of an organ of sense. *Perception* is the cognizing of the object which produces the sensation.

2. *The Senses*. The *internal senses* are the central or synthetic sense, imagination, sense memory, and instinct. The external senses are sight, hearing, taste, smell, and the somesthetic senses. The somesthetic senses are the cutaneous senses of pressure, pain, warmth, and cold, and the intra-organic senses, i.e., the visceral sense, static sense, and kinesthetic sense. Sight, hearing, taste, smell, warmth, cold, pressure, and pain are *exteroceptive*; the visceral and static senses are *interoceptive*; and the kinesthetic sense is proprioceptive.

3. *The Cutaneous or Skin Senses*. The cutaneous senses are located in the skin region, and they are the senses of pressure, pain, warmth, and cold. The skin contains various types of nerve endings associated with the cutaneous sensations: *capsules, Pacinian and Meissner corpuscles, Krause bulbs, and the end organs of Ruffini*.

4. *The Sense of Pressure*. The stimulus is anything which, upon contact, alters the even surface of the skin.

Hair follicles serve as receptors of touch and pressure; most likely also Meissner corpuscles and perhaps free nerve endings.

5. *The Sense of Pain.* The stimulus is some object which injures or nearly injures nerve tissue. The pain receptors are the free nerve endings.

6. *The Temperature Sense.* It is still somewhat uncertain whether this is a single sense or whether there is a distinct sense of warmth and a distinct sense of cold. Most probably they are separate and distinct senses. Investigators associate the sensation of cold with the Krause bulbs and that of warmth with the end organs of Ruffini; others look for the true stimulus source in the blood vessels. The sensation of 'heat' results from the stimulation of adjacent warmth and cold spots.

6. *The Visceral Senses.* The visceral senses and the static sense are *interoceptive*. The *visceral senses* have the source of their stimuli in the viscera or vegetative organs. There are several kinds of visceral *sensations*: some pertain to the musculature, some to the nutrition system, some to the digestive tract, and some to the respiratory and circulatory systems. It is doubtful whether any special senses participate in visceral sensations; apparently, the receptors of pressure, pain, cold, and warmth combine in various patterns and thus give rise to visceral sensations.

8. *The Static Sense.* It is an intra-organic sense, the end organs of which lie in the internal ear and are stimulated by the pull of gravity and by head movements. The organ consists of the semicircular canals, ampullae, utricle, and saccule. The canals, with their endolymph, acquaint us with

the *rotary movements* of the head. The utricle and saccule, with their otoliths, acquaint us with any deviations of the head and body from their normal *positions*. The static sense is a sense of positional equilibrium and orientation in head movements.

9. *The Kinesthetic Sense*. It mediates sensations of the position and of the active and passive movements of *the bodily members*. We also experience sensations of resistance and weight. The *organs* are probably muscle spindles and tendon spindles. Corpuscles of Ruffini and Pacini, in all probability, also play a part in these sensations.

Chapter 5

SMELL, TASTE, HEARING

SMELL AND TASTE ARE 'CHEMICAL SENSES' BECAUSE THEY ARE activated by chemical stimuli. They are also reckoned, together with the somesthetic senses, among the 'lower' senses, while hearing and sight belong to the 'higher.' Smell and taste have more of a nutritive value, while hearing and sight have more of a cognitive value, and nutrition is of a lower order than cognition. Since the logical procedure is to pass from the lower to the higher, smell and taste must be discussed first, then hearing and sight.

The Sense of Smell

Smell is the sense by which certain properties of bodies (called their smell, odor, or scent) become known through the stimulation of receptors responsive to chemical substances in a gaseous form or to minute particles which reach them normally from a distance and in low concentration.

The *organ* of smell is a brown-yellow spot of the mucous membrane of the nose, about the size of a ten-cent piece, situated in a little pocket above the ordinary nostril

chamber and connected with it through a narrow cleft. Its location places it apart from any direct contact with the inhaled and exhaled air and protects it against dust, insects, etc., and also against sudden changes of temperature. Odorous particles mingle with the air and are inhaled into the nostrils through breathing; they then reach the olfactory spot through diffusion or through eddies in the air currents produced by sniffing. Foods and liquids taken into the mouth also give off odorous particles which are exhaled with the breath; a part or all of this exhaled breath is forced up into the nasal cavities from the rear of the mouth, and in this manner the olfactory receptors are stimulated by the odor of foods and liquids. The receptors are nerve cells situated within the membrane of the olfactory spot; slender nerve endings (dendrites) reach out from the cells peripherally to the membrane surface, while axons of the cells extend inward to the olfactory bulb at the base of the brain, where connections are made with the olfactory center in the cerebrum.

Fig. 17. Organ of Smell.

A. Relative position of the olfactory organ and the nasal cavity. — B. Enlarged cross section of the receptor cells.

The *stimulus* for the sense of smell is a gas in which odorous *particles* are suspended. Formerly it was thought by some that objects send off vibrations to the nose and thereby produce the sensation of smell; and the reason for this view was the alleged fact that certain strongly odorous substances, such as musk, apparently lost no weight even over long periods of time. It is now known that minute particles are released from such substances at all times. The vibration theory has received a positive refutation through the fact that a complete stoppage of the nasal cavities excludes completely the sensation of smell, although vibrations may still reach the interior of the nose. It is now universally accepted that solids and fluids must volatilize before their odorous qualities can be sensed. Usually the minute particles thus liberated mix with gaseous air and thus influence the sense organ. E. H.

Weber filled the nasal cavities completely with eau de cologne and experienced no sensation of smell; eau de cologne must volatilize and diffuse into the air before it can act as a stimulus.

Some vapors and gases are odorous; others are not. It seems that the *chemical constitution* of a substance and the *specific receptivity* of the receptor cells determine whether a particular substance can arouse a sensation of smell and what kind of smell. The pure elements, with the exception of the halogens (fluorine, chlorine, bromine, iodine), are non-odorous. Most odorous substances are carbon compounds. It is estimated that only sixteen elements enter into combinations which emit odors perceptible to man. Arranged according to the chemical families to which they belong, these are: hydrogen; carbon, silicon; nitrogen, phosphorus, arsenic, antimony, bismuth; oxygen, sulphur, selenium, tellurium; fluorine, chlorine, bromine, iodine. Similar compounds within a chemical family usually possess similar odorous qualities. The quality of a substance, determining whether or not it can act as a stimulus for smell, depends apparently upon the atomic or molecular grouping of a substance. In accordance with this view, some scientists have proposed the theory that *electronic oscillation* is the stimulus for the sense of smell; thus Haycraft, Heyninx, and Zwaardemaker. This theory is interesting, but as yet it lacks experimental verification to a considerable degree. It is plausible that the organ of smell is a composite organ, consisting of different types of cells with specific reactions. Rollett induced a total anosmia (lack of the sense of smell) in himself; as the anosmia waned,

smell revived gradually and that in a very definite order. Similarly, when the organ of smell becomes fatigued through overstimulation from a particular odor and responds sluggishly, it will also respond sluggishly to odors related to the first. Partial destruction of the sense of smell occurs, so that certain types of odors are eliminated while others can still be sensed.

Concerning the *classification of odors*, no system has been devised which gives complete satisfaction. Linnaeus (1756) was the first to make an attempt at a scientific classification. He enumerated seven fundamental types of odors: aromatic (typical: carnation), fragrant (lily), ambrosial (musk), alliaceous (garlic), hircine (valerian), repulsive (some bugs), nauseous (rotten meat). Zwaardemaker (1925) added two classes to the list of Linnaeus, placing 'ethereal' odors at the head before the aromatic odors and 'empyreumatic' odors after the alliaceous; ether is an example of the ethereal group, and roasted coffee of the empyreumatic group. He also subdivided the various classes and endeavored to find a place for the odorous compounds of organic chemistry. The four at the beginning of the list are 'nutritive' odors, the rest 'decomposed' odors. Henning (1924), after extensive experiments with no less than 415 odorous substances, arrived at the following classification:

Fragrant — heliotrope, etc.

Fruity — apple, etc.

Resinous — turpentine, etc.

Spicy — cloves, etc.

Putrid — carrion, etc.

Burned — coffee, etc.

Much experimentation with odors has been done, and some phenomena are noteworthy. *Fatigue*, with *adaptation* to the stimulus, is common. Continued exposure to the same stimulus weakens the sensation, if the stimulus is strong; if the stimulus is a mild odor, sensation usually disappears completely. The *mixture* of odor stimuli produces diverse results. In most cases, one experiences a blend of odors; the components are individually perceptible, though the total impression is unitary. In the case of a great dissimilarity between two component stimuli, the usual experience is to sense first the one, then the other, successively. Another phenomenon which occurs, according to some investigators but denied by others, is *compensation* or *neutralization*. Some stimuli, when combined, simply cancel out each other. It is claimed that the stimuli of caoutchouc and wax or paraffin neutralize each other.

One often speaks of odors which are 'sweet,' 'sour,' 'pungent,' 'bitter,' etc. These are, in all probability, not qualities of odors as such. End organs for pressure, pain, cold, and warmth are located in the nostrils and in the rear portion of the mouth, and it is obvious that they, too, are stimulated by odorous gases; combined sensations are the result. If the sense of taste is eliminated, chloroform no longer smells 'sweet'; and if the sense of smell is eliminated, the sweetness of chloroform remains. Taste and smell, due to the close proximity of their end organs and the similarity of their stimulation as chemical senses, are intimately

connected in function, so that the stimulus of the one is frequently referred to the other. In ordinary life, it is practically impossible to separate the two.

The Sense of Taste

Taste is the sense by which certain *qualities* (taste, savor, flavor) *of soluble substances become known by contact with a particular set of epithelial end organs* (taste buds) *located mainly in the papillae of the tongue.*

The *organs* of taste are the *taste buds*, and they are present in great numbers in pimple-like protuberances called papillae. These papillae are found mainly on the tip, sides, and rear portion of the tongue, but some also in the soft palate and in the throat; the middle portion of the tongue is devoid of taste sensitivity.

The *stimuli* are chemical substances which must be *soluble* to some extent; insoluble substances are tasteless. Vapors and gases can be tasted; ordinarily, however, substances enter the mouth in a solid or fluid condition. Upon contact with the tongue, particles in solution seep down from the surface of the tongue through little crevices or canals into the interior of the taste buds and there stimulate the actual *taste cells*. Pressure of the tongue against the roof of the mouth facilitates stimulation by forcing the solution into the taste buds. The brushlike endings of the sensory nerves in the taste buds carry the impulse along the lingual and glossopharyngeal nerves to the gustatory center of the brain.

As in the case of the sense of smell, the sensations of taste very rarely appear alone; they are mixed with those of smell and with those of the cutaneous senses. It is difficult to eliminate these extraneous components; but when they are eliminated, it is found that the *number of sensations* is no more than four: *sour, salty, sweet, and bitter.*

Such, at least, is the general opinion today. There are not even subgroups or variations of these four. Substances of the same concentration always have the same sour, salty, sweet, or bitter taste, whatever happens to be the flavor of these particular substances. When we speak of a 'hot,' 'cool,' 'pungent,' 'astringent,' taste, etc., one or the other or several of the cutaneous senses are certain to be involved as component factors.

The *localization* of the various tastes shows that they are distributed unevenly. While some papillae respond only to sour or to bitter or to sweet, others respond to two or three kinds of stimuli, and many to all four. Definite areas of the tongue are more sensitive to one kind of stimulus than to another. Experimentation proves that sensitivity to sweet is strongest at the tip of the tongue and decreases gradually in strength toward the back; the sensitivity to bitter is strongest in the rear portion of the tongue and becomes gradually weaker toward the front; the sensitivity to sour is strongest at the edges in the middle of the tongue and

Fig. 18. Organ of Taste.
A. Cross section of the tongue.—
B. Taste bud (greatly enlarged).

weakest toward the front and back; sensitivity to a salty flavor is strongest toward the front and side areas of the tongue. One kind of taste is independent of the other because one kind can be impaired and even lost without affecting the others.

This evidence seems to warrant the conclusion that there are *four types of receptors* in the sense of taste, so that certain receptor cells in the papillae respond only to certain stimuli. Many physiologists assume that the hydrogen ion is the stimulating agent in the sour taste, and the anion in the salty taste, while sweet and bitter substances react with the lipoid (fatlike) substance present in the taste cells. It is a probable theory that the four principal tastes are the result of a chemical reaction between four receptive substances in the cells and the sapid substances placed upon the tongue. That the physiological process is chemical in nature, is without doubt; but the exact details of the process are still very obscure.

Adaptation is a common phenomenon in taste sensations, as everyday experience proves. A sweet solution tastes sweetest at first contact; afterward it tastes less sweet. The concentration of a solution must be increased many times after adaptation before the sensation can be aroused again. Adaptation varies. It is least in the case of sour and salty solutions, greater in the case of bitter, and greatest in the case of sweet.

Individually and in their combination, the senses of smell and taste enable us to recognize many properties of substances and thereby the substances themselves. Their

primary purpose is obviously to supply us with the necessary cues to distinguish between what is good or harmful for the organism in the line of food and drink. Bitter substances, for instance, have lower threshold values than sweet; that is to say, it takes a much smaller amount of bitter than of sweet substances in order to arouse sensation. The majority of bitter substances are alkaloids and therefore frequently poisonous, while sweet substances are usually energy giving and as such beneficial. We shun the bitter and crave the sweet; the difference in threshold value thus manifests biological purposiveness.

The Sense of Hearing

Hearing is the sense by which the *vibrations of certain media acting upon the ear become known as sounds*. The human ear is a marvelous neural mechanism. Consider a symphony orchestra with its manifold types of instruments, its constantly progressing and changing melodies, its shifting keys and chords, its harmonies and dissonances, its slow and rushing tempos, its whispering pianissimos and thundering fortissimos — the ear is capable of detecting, distinguishing, and analyzing all these confusing factors with a nicety and assurance that is truly amazing. A minute piece of organic structure in the head thus reacts selectively to a veritable flood of intermingling air waves emanating from vibrating bodies. It is but natural, therefore, that physicists have made an intensive study of sound waves, that anatomists have subjected the ear to a thorough microscopical examination, that physiologists

have endeavored to trace the function of hearing from start to finish, and that psychologists have conducted innumerable experiments in auditory sensation and perception.

Since the ear is the organ of hearing and hearing is the power or act of detecting sound, it is important to understand precisely what is meant by *sound*, because the physicist and the psychologist attach a different meaning to the term 'sound.' To the *psychologist* 'sound' is a *sensation* caused by the stimulation of the auditory nerves and the auditory center of the brain. To the *physicist* 'sound' is a form of vibrational energy transmitted through an elastic medium (e.g., air) in external nature. The physicist considers 'sounds' to be identical with the 'vibrations' in so far as they proceed from a vibrating or 'sounding' body and travel through a medium, irrespective of whether or not they are heard by an ear. The psychologist, on the other hand, considers 'sound' to be identical with the conscious experience of tonal qualities' resulting from the stimulation of the neural mechanism of the organ of hearing, after the stimulus (the sound wave of the physicist) has acted upon the organ. The viewpoint of the physicist is that of one studying the external objective *agent* which eventually arouses the sensation of hearing, while the viewpoint of the psychologist is that of one examining the internal subjective act of *conscious response* to this external objective agent. Both viewpoints are legitimate. In order to avoid a confusion of ideas, however, it is well to know this difference in meaning. In the following discussion both

meanings occur, and the context shows which of the two is intended at the moment.

It will be necessary to touch on the main features brought to light on the mechanism of the *human ear*, on the nature of *physical sound*, and on the *relationship between the two*.

The Human Ear

The *organ* of hearing is the *ear*. In man the ear consists of three distinct parts: the *outer ear*, the *middle ear*, and the *inner ear*.

The *outer ear* of man is designed to collect sound waves and transmit them to the middle ear. One part of the outer ear is the shell-like or trumpet-like structure, called the *pinna* or *auricle*, which extends outward from the side of the head. Man has muscles in his ears which indicate that he was able at one time, no doubt in the far past, to move them for directional purposes. In the vast majority of human beings these muscles are atrophied, so that the external ears are of little use. More important for hearing is the canal, or *external auditory meatus*, which leads into the interior of the head and permits the air waves to come into contact with the ear drum. The *ear drum*, or *tympanic membrane*, is a membrane which stretches across the external meatus like the head of a drum and thus closes off the inner end of the external meatus and separates it from the middle ear.

Fig. 19. The Human Ear.

The *middle ear* is an air-filled cavity within the skull, situated immediately behind the tympanic membrane. This membrane, therefore, is the end of the external ear and the beginning of the middle ear. The air waves, passing along the external auditory meatus, strike against the tympanic membrane and produce vibrations in it which correspond to the vibrations in the air. From the tympanic membrane these vibrations are now carried forward by *three small bones*, or *ossicles*, across the cavity of the middle ear. The first of these bones is the *hammer*, or *malleus*. The handle of the malleus extends down toward the center of the tympanic membrane, where it is permanently attached. The second bone is the *anvil*, or *incus*, which is attached to the head of the hammer. The incus has a tapering prolongation, the lower extremity of which is attached to the *stirrup*, or *stapes*, the third bone in the series. The stirrup, on its part, is attached to the membrane of the *oval window*, or

fenestra ovalis, of the internal ear. The arrangement and articulation of these three small bones is an ingenious contrivance of levers, to transmit the vibrations of the tympanic membrane across the space of the middle ear to the inner ear and also to absorb any injurious shocks. The inner ear, the real organ of hearing, is a delicate mechanism. The tympanum is often exposed to explosive shocks of excessively strong air waves, so that a direct contact between the tympanum and the inner ear might do serious harm. The ossicles act as shock absorbers, while serving as vibration communicators between the tympanum and the inner ear. In order to equalize the air pressure on both sides of the tympanic membrane and thus protect it against rupturing, a tubal opening connects the middle ear with the posterior portion of the nasal cavity; this opening is the 'eustachian tube.'

By means of the three ossicles, vibrations reach the *inner ear*. The inner ear contains a number of structures: the semicircular canals, the vestibule, and the cochlea. The semicircular canals have nothing to do with the sense of hearing, but are a part of the static sense; the cochlea belongs exclusively to the sense of hearing; the vestibule belongs to the static sense, but it also has an important function in connection with hearing.

The inner ear is completely surrounded by the bone structure of the head, except for a portion of the vestibule which borders on, and is exposed to, the cavity of the middle ear. All the organs of the inner ear are enclosed in a bony casing. The casing is pierced in the region of the middle ear by two openings which are covered by

membranes: the 'oval window' or *fenestra ovalis*, just mentioned, and the 'round window' or *fenestra rotunda*. The purpose of these two membrane-covered openings will soon be described.

The *cochlea* contains the real organ of hearing. It is a bony casing or housing, shaped spirally like a snail's shell; hence the name. Its spiral has two and one half turns and is built around a conical bony core, the *modiolus*. The cochlea is divided throughout its entire length into two main sections by means of the *basilar membrane* which stretches transversely across the cochlear cavity from the modiolus to the outer casing. The two channels formed thereby are the *vestibular canal* and the *tympanic canal*. The vestibular canal ends at the 'oval window,' while the tympanic canal terminates at the 'round window.' At the upper end or apex of the cochlea, both canals are in communication with each other through a small opening, the 'helicotrema.' The vestibular and tympanic canals are filled with a fluid called *perilymph*. The function of this fluid is evident. When the stirrup communicates its vibrations to the membrane of the 'oval window,' this membrane, in turn, relays the vibrations to the perilymph of the vestibular canal; through the helicotrema these vibrations pass over into the tympanic canal; in this manner the vibrations travel from the base of the cochlea to the apex and from the apex back to the base and to the membrane of the 'round window.' Since liquids are practically incompressible, the membrane of the 'round window' must equalize the pressure exerted upon the membrane of the 'oval window' by the vibrating stirrup

bone. The minute vibrations are thus transmitted through the perilymph with full vigor.

Fig. 20. Cross Section of the Organ of Hearing.

A. Cross section of the cochlea (enlarged).—B. Cross section of the organ of Corti (greatly enlarged).—C. Receptor cell (very much enlarged).

There is, however, a *third canal* in the cochlea, the most important of the three canals. It is triangular in shape and is formed by the *membrane of Reissner*. This membrane runs from the cochlear casing at an angle to the basilar membrane, near the point where the basilar membrane is joined to the modiolus. The base of the triangle is thus the bony casing of the cochlea, and the two sides of the triangle, converging to a point near the modiolus, are the basilar membrane and the membrane of Reissner. A part of the vestibular canal is thus cut off to form this third canal, the *cochlear canal* or *ductus cochlearis*. Its location is between the vestibular canal and the tympanic canal, and it, too, runs through the entire length of the spiral. The cochlear canal is filled with a liquid called the *endolymph*, the purpose of which is to take up the vibrations

transmitted through the perilymph to the Reissner membrane and carry them to the 'organ of Corti.'

The Organ of Corti

The *organ of Corti* is the *neurological organ of hearing*. It is to the ear what the retina is to the eye. All the structures described so far are accessory structures leading the vibrations of the sonorous bodies to the actual organ of hearing, the organ of Corti.

The organ of Corti is situated on the *basilar membrane* in the cochlear canal. Transverse fibers, estimated at about 24,000, are stretched across the basilar membrane; they vary in length, the longest being about three times the length of the shortest. The organ of Corti is microscopical in size. In it are found the *receptor cells* of hearing, resting on the transverse fibers of the basilar membrane. These cells are 'hair cells'; that is to say, certain hair-like terminations protrude from them, and these 'hairs' are embedded in the *tectorial membrane* which extends out into the endolymph nearly halfway across the canal. Whatever vibrations pass through the endolymph bend these 'hairs' back and forth. In this manner the vibrations act as a stimulus for the hair cells; a nerve impulse is produced in the nerves terminating in the cells; these auditory nerves pass through the modiolus, make their exit at the base of the cochlear spiral, form the eighth cranial nerve, and go to the midbrain and from there to the superior gyrus of the cerebral cortex. The result of this nerve impulse is the *sensation of sound*.

From this description of the outer, middle, and inner ear it is obvious that the air vibrations, taken up by the outer ear, never reach the cochlea and the organ of Corti. The air vibrations become vibrations of the ear drum; these become vibrations of the three ossicles, the hammer, anvil, and stirrup; these become vibrations of the membrane of the oval window; these become vibrations of the perilymph in the vestibular and tympanic canals; these become vibrations of the membrane of Reissner; these become vibrations of the endolymph of the cochlear canal; and these vibrations are the proximate stimulus for the receptor cells of the organ of Corti. While the air vibrations are the normal ones to start the chain of vibrations which eventually lead to the hearing of sound, they are not strictly necessary. People whose outer or middle ear is very defective can hear if the vibrations are transmitted to the cochlea through the bones of the head. Vibrations are necessary for hearing, but they need not be vibrations of air.

Sound as Sensation

Upon stimulation of the receptor cells in the organ of Corti, the nerve impulse produced there travels up to the auditory center of the cerebrum. We now *consciously experience sound*; this conscious experience of sound is what is meant by the sensation of sound or *sound as sensation*. In considering sound sensation, we are not interested in the type of vibration which acted as the stimulus for arousing the receptor cells, but merely in our conscious experience

which is the end result of this stimulation; in other words, we are interested in the conscious effect, not in the physical cause.

Viewed from this standpoint, we are conscious of *two main kinds* of sounds: *tones* and *noises*. There is a fundamental difference between the two kinds, although we usually encounter a mixture of both. As given in our subjective experience, 'tones' are something clear, musical, agreeable, while noises are more or less harsh, unmusical, disagreeable. One need but think of the preliminary tuning-up exercises of a band just prior to playing, and the actual rendition of a concert piece, in order to understand the difference between noises and 'tones.'

Sounds, considered psychologically, have *three chief characteristics*: pitch, loudness, and timbre.

Pitch. The pitch of a sound is designated by the expressions *high* and *low*. These expressions are metaphors taken from spatial dimensions; we have no literally direct terms to designate 'pitch' as a sound quality. The expressions, however, are apt enough. No doubt, the terms 'high' and 'low,' as applied to the psychological experience of sound, have their origin in the association with volume and dimension. There is something broad, voluminous, massive, dark about the 'low' sounds; sounds lose more and more of this character as the scale advances, until they become thin, sharp, light, bright in the 'high' sounds. The progress from the bottom to the top of the scale of sounds resembles the ascent from the deep broad lowlands of the valleys to the high narrow tip of a mountain peak. Some such association probably prompted the selection of the

terms 'low' and 'high' as analogically descriptive of the pitch of sounds.

Sounds having a definite, well marked pitch are called *tones*. Sounds produced by musical instruments and, as a rule, by the animal voice, are tones. Not always, however; a sneeze, a cough, the bark of a dog, and the roar of a lion are noises. *Noises* also have pitch. An exploding firecracker has a higher pitch than a bomb. Language appropriately describes the difference of pitch in noises by means of words: squeak, slither, blare, rattle, noise, shot, roar, rumble, boom.

The *range* of the human ear and its *selective discrimination* of pitch is remarkable. Sensitivity differs in individuals to some extent, but the average person is capable of distinguishing about 20,000 different tones. Pitch sensitivity is a native endowment, but attention and practice sharpen the acuity of discrimination; it is best in the middle section of the scale, and not so good in the lower and higher sections.

Loudness. Loudness, like pitch, is uni-dimensional; that is to say, it is progressive in character, beginning with sounds so weak as to be barely audible and increasing in strength until sounds of maximum intensity are reached.

Timbre. Timbre, or tone color, is that quality which *distinguishes tones of the same pitch*, when produced by different voices or instruments. For example, when instruments are being tuned for a concert piece, the pianist will strike a certain note on the piano. This same note will then be played by other musicians on the violin, the clarinet, the flute, the trumpet, the oboe, etc. The pitch of

the tone is the same for all the instruments; yet this same tone is characteristically different for each instrument. And if a number of singers give voice to this same note, it will be noticed that their tones are individually different. A musician can always recognize the type of instrument by its tonal quality. It is this tonal quality which is designated as tone color or timbre. In the description of tones, words like 'soft,' 'metallic,' 'wooden,' 'mellow,' 'thin,' 'full,' 'hollow,' 'sweet,' 'clanging,' etc., express timbre.

Timbre is the result of a fundamental tone combined with harmonic *partials or overtones*. Tones as we hear them are practically never simple, pure tones, but tones compounded of a dominant (fundamental) tone and a number of other tones (partials or overtones) which have a definite harmonic relation to the dominant tone. Close attention to tones as emitted by various instruments enables a trained listener to pick out the fundamental and also the distinctive overtones, although in normal experience, leaving critical analysis aside, the tone as a whole is sensed as a *unit*. The number and strength of the partials, therefore, determine mostly the timbre of a voice or instrument. Various kinds of *harmonic analyzers* have been devised to discover the overtones accompanying the fundamental tone; these analyzers show that the timbre of instruments depends on the number and strength of the overtones. Over 40 partials can be detected in the low notes of a piano, and in the clarinet some of the partials constitute about 60 per cent of the tone. The timbre of the same instrument changes considerably in the low, middle, and

high registers. Timbre, then, is a matter of overtone structure more than anything else.

Sound as Vibration

So far we have considered sound as a psychological experience, as sensation. Sound, however, has a *physical cause*; it is not something purely subjective. The physical correlate of the sensation of sound is the *vibration* of air or of some other medium. Such vibrations determine the pitch, the intensity, and the timbre of the sounds we hear, because they are the *physical stimulus* of the organ of hearing, and sensation is a conscious response to a physical stimulus.

From the standpoint of physics, *sound* is a form of vibration, *a wave motion in an elastic medium*. The sound wave is a *longitudinal vibration*, the particles of the medium moving back and forth, not in a curve, but in a straight line. In air, which is the common medium of physical sound, this wave is produced by a condensation and rarefaction of the air. The waves proceed from the sounding body in all directions, so that they represent an ever-widening sphere. Sound waves travel through the air with the speed of about 1100 feet per second, depending on the density of the air. They follow one another at a certain frequency, and by 'frequency' we mean the number of vibrations per second. The *energy* of the stimulus determines the *amplitude* of the *vibration*, and that is its *intensity*.

Psychologically, sounds are experienced as having pitch, loudness, and timbre. Since sensation is the conscious response to a physical stimulus, and since the physical

stimulus is the sound wave or vibration, what in the stimulus corresponds to pitch, loudness, and timbre? To put it in a different way:

How do sound waves or vibrations produce the pitch, loudness, and timbre of sounds as experienced in sensation?

Pitch and Sound Waves. Extensive experimental research has established the fact that *pitch* is determined by the *vibration rate or frequency*. A low rate produces low sounds a high rate, high sounds. Middle C, for example, has a vibration rate of 260 vibrations per second; this rate is expressed in a different manner by saying that the frequency of these waves is 260 cycles per second. The octave below middle C has a rate of 130 vibrations per second, and the octave above a rate of 520. The lowest sound still audible by the human ear has about 16 to 20 vibrations, while the highest has about 20 to 21,000 vibrations per second. Individuals differ, of course, in sensitivity, and absolute figures are thus impossible; the figures given are those of the most reliable authorities. Young persons have a larger range than older persons. Sensitivity is not uniform in all registers, so far as the distinction of differences in tones is concerned; it is finest in the middle registers, where sounds have a vibration rate of from approximately 1000 to 5000 per second. Many persons are able to distinguish tones with a difference of only four vibrations, and a trained ear can notice the difference between half a vibration and even less. A semitone is one twelfth of an octave and has about 16 vibrations at middle C; this interval is relatively large and is

easily distinguishable. It is claimed that in the middle octave as many as 1000 tones can be discerned as to pitch, at least by very keen ears.

Loudness and Sound Waves. The *loudness* of tones is dependent on the *amplitude* or *intensity* (energy) of the vibration. The vibration rate or frequency of a sound wave remains the same at all times, unless impeded in some way, and the pitch, therefore, also remains the same. The amplitude or energy of a sound wave does not remain the same; unless reinforced constantly, energy is gradually used up, so that the amplitude decreases as time goes on. Thus, a tuning fork whose note is middle C will always give off this tone, because its vibration rate or frequency is always 260 cycles per second as long as it vibrates; its amplitude or energy, however, diminishes gradually, and the tone becomes weaker and weaker in loudness, until it finally ceases altogether. The greater the amplitude of the sound wave, therefore, the louder the tone; the smaller the amplitude, the weaker the tone.

Pitch is determined by frequency, vibration rate; loudness, by amplitude, intensity, energy. It would be erroneous, however, to give an absolute value to this rule. The organ of hearing is not a machine which responds mechanically to a mechanical stimulus. Hearing is the function of a living organ, and this function modifies to some extent the operation of the rule. Since the sensitivity of the organ of hearing is finest in the middle range (1000 to 5000 vibrations per second) and weaker in the low and high ranges, sound waves in the low and high ranges must have greater energy than in the middle range in order that

the sounds be equally loud to the ear. The voice of a soprano will appear louder than that of a bass singer, even though the intensity of both voices be the same. Similarly, octaves have the ratio of one to two as to frequency; psychologically, in the low and high registers, the octaves seem to have a smaller span than in the middle region of the musical scale. The semitones represent the same interval in all octaves, and this interval should be heard as the same in every octave; but that is not the case. If two adjacent keys are struck successively at the lower and upper end of the keyboard of a piano and then in the middle of the keyboard, the interval between the semitones in the middle register will appear greater than that of the semitones at both ends. Pitch and loudness, therefore, are not rigidly determined by the frequency and amplitude of the vibrations, but depend to some extent on the unequal sensitivity of the ear.

Timbre and Sound Waves. Timbre, as was said before, is a mixture or blending of a fundamental and overtones. In sounds produced by musical instruments these overtones stand in a harmonic relation to the fundamental, namely, in the ratio of 1, 2, 3, 4, etc. The reason is the fact that a sounding body vibrates not only as a whole but also in its parts. When a violinist draws the bow over a string, the string vibrates as a whole, and that gives rise to the *fundamental*. But the string also vibrates by halves, quarters, eighths, etc., each part having its own frequency relative to the others; these vibrating parts thus give rise to *partials or overtones*. These overtones also have *different*

intensity quantities; some are stronger, some weaker. Frequency means pitch; intensity means loudness.

It is the blending of these overtones of different pitch and intensity with the fundamental of the string as a whole which constitutes the timbre of the violin. The material and construction of the instrument as a *resonator* for the tones contribute greatly to this timbre, because the body of the instrument vibrates also in its own peculiar manner, damping some tones and reinforcing others. The tuning fork, being so simple in construction, emits a relatively simple and pure tone.

Noises and Sound Waves. That noises and tones are not essentially different is clear from the fact that tones are present in all noises. Noises are combinations of tones; these tones can be separated through sound filters and eliminated individually. Being combinations of tones, noises consist of a number of fundamentals with their respective partials; this combination brings about a *conflict of frequencies and amplitudes* among the component tones which affects the ear disagreeably because of interference among their proper ratios. Noises are somewhat in the nature of timbre, except that the parts are combined in a disharmonious whole; hence some instruments, particularly drums and certain horns, are more noisy than musical.

The Musical Scale. A 'tone is a sound with a well-marked or definite pitch. A *musical tone* is one which has a definite harmonic relation to other tones, so that it can be combined with them into harmonies and melodies. A *harmony* is the simultaneous combination of musical tones which gives pleasure to the listener. A *melody* is the rhythmical

succession of single musical tones arranged into a pleasing unity. A *musical scale* is a graduated series of tones, ascending or descending in order of pitch according to a specified scheme of their intervals. The typical interval scheme of the modern scale of music is the octave. In the 'chromatic' scale there are twelve equal steps or intervals (semitones) between a keynote and its octave, based on the frequency of the sound waves. It is indifferent what particular vibration be chosen as a keynote; but once a keynote has been selected, the intervals progress in a definite ratio of vibrations up to the octave. By international agreement the tone of 440 cycles (vibrations) per second is designated as 'a'. Since the octave above a chosen keynote stands to this keynote in a frequency ratio of 2 to 1, it is obvious that the vibration rate of this octave must be 880 per second. By multiplying 440 by 1.059 and dividing the product by the twelfth root of 2, we arrive at the vibration rate of each of the twelve semitones in this octave. In order that tones be 'musical,' so that they can be combined in harmonic relations with one another, they must be 'spaced' or separated from one another by definite distances in the scale. Because of this fact, only about 85 tones are available for musical purposes, so that there are only 7, or at the most 8, octaves in the musical tone system which can be effectively used by musicians.

Theories of Hearing

A relationship undoubtedly exists between physical sound waves and the pitch, loudness, and timbre of sounds as

experienced in the organ of hearing. From time to time theories have been advanced attempting to explain this relationship.

The Resonance Theory. This theory is associated with the name of the eminent scientist *Helmholtz*. To him and his followers the basilar membrane of the cochlea, with its more than 20,000 transverse fibers, is similar to a piano with its many strings. When the damper is lifted and a note is sung into the piano, this note is an air wave compounded of many frequencies, and each string which corresponds to one of these frequencies will vibrate. In this manner the fundamental and partials of the voice tone is reproduced through *resonance* in the strings of the piano. In an analogical fashion the fibers of the basilar membrane are individually attuned to the frequencies of the sound waves, each to its proper frequency. The membrane is narrowest at the base of the cochlea and widest at the apex; it is therefore assumed that the 'resonators' for the high sounds are at the base and those for the low sounds at the apex. The vibrations communicated to the endolymph thus affect the transverse fibers and stimulate the 'hair cells' attached to them, and the impulse is transmitted from each cell through a conducting nerve fiber to the brain. Pitch would be explained by the rate of vibrations, loudness by their energy, and timbre by the complex of vibrations of the sound waves producing a similar effect in the transverse fibers.

Evidence of a sort for the resonance theory is found in the cases of *tone deafness due to localized injury* in the organ of Corti. Injuries make people deaf to tones of a

certain frequency band, depending on the region affected. On the other hand, objection is raised against the theory on the basis of the *microscopical dimensions* of the transverse fibers; it is difficult to understand how a correspondence can exist between the relatively large sound waves and the infinitesimal fibers.

The Sound-Pattern Theory. In this theory, the basilar membrane as a whole reacts to the incoming vibrations in such a manner that it vibrates in patterns which correspond to the *sound patterns*. Accordingly, some sections of the membrane vibrate while others are at rest, and the type of vibration varies in the different sections, so that the neural current is the exact counterpart of the sound pattern.

Considering the rapid changes which occur in the sound patterns of, let us say, a spirited concert piece, it seems doubtful whether the *refractory phase* of a nerve impulse would permit such rapid changes and impulses without serious interference. To offset this difficulty, some adherents of the sound-pattern theory, especially *Wever and Bray*, contend that it is not necessary to suppose that the single nerve fiber responds to every successive wave, but only, perhaps, alternately or at certain intervals. To use the analogy of a company of soldiers firing their rifles, certain squads may fire a volley in rotation instead of the entire company firing at once. This so-called *volley theory* is based on the plausible assumption that the refractory phase is not the same for all nerve fibers, so that some fibers can transmit the impulse while others are in their refractory phase.

Neither the resonance theory nor the sound-pattern theory seems capable of explaining all the facts. Perhaps neither is an adequate interpretation of hearing. On the other hand, the two theories are not mutually exclusive in their main features, and it is possible that both contain elements of truth which can be united in a serviceable theory. Some psychologists favor the view that a composite theory, combining the resonance and sound-pattern ideas, is the best.

SMELL, TASTE, AND HEARING ARE IMPORTANT SENSES. THEY convey to the organism many items of information concerning things as they exist for themselves. These senses, like the somesthetic senses, enable man to make a *proper adjustment to his environment*, and this is the main purpose of the cognitive element in sense function.

One important fact should be noted. There is *no mechanical point-for-point correspondence* between sense and stimulus. The senses are *selective* in their response to possible stimuli. Taste, for example, responds in just four ways to the manifold chemical properties of things; pitch and loudness are not mechanical reproductions of the frequency and amplitude of sound waves. Vital function is thus seen to be distinct from mere physical action. Furthermore, these senses, especially the closely cooperating smell and taste, plainly show again that man is an *integral organism*, because their functions are not isolated activities but are subservient to the welfare of the organism as a whole.

Summary of Chapter V

Smell and taste belong to the 'lower' senses, hearing and sight to the 'higher'; the former are nutritive, the latter are more cognitional in character.

1. *The Sense of Smell.* It is the sense by which certain properties (smell, odor, scent) become known through the stimulation of receptors responsive to chemical substances in a gaseous form or to minute particles which reach them normally from a distance and in low concentration. The *organ* of smell is a small brown-yellow spot of the mucous membrane of the nose. The *stimuli* are odorous particles which enter the nostrils through the breathing in of some form of gas in which the particles are suspended. The odorous quality of substances depend on the chemical constitution of the substances and on the specific receptivity of the receptor cells.

Among the many *classifications* of odors, the following is the one generally accepted: fragrant, fruity, resinous, spicy, putrid, burned.

2. *The Sense of Taste.* It is the sense by which certain qualities (taste, savor, flavor) of soluble substances become known by contact with a particular set of epithelial end organs (taste buds) located mainly in the papillae of the tongue. The *organs* of taste are the taste buds. The *stimuli* are chemical substances in solution. The *kinds* of taste are four: sour, salty, sweet, and bitter. In all probability there are four types of receptors corresponding to these four kinds of taste.

3. *The Sense of Hearing.* It is the sense by which the vibrations of certain media acting upon the ear become known as sounds.

‘Sound’ has two distinct meanings: physical and psychological. *Physical sound* means the vibrations emanating from a vibrating body. *Psychological* sound means the conscious experience of tonal qualities after the organ of hearing has become activated by the stimulus of the vibrations.

4. *The Human Ear.* The ear is the *organ* of hearing. In man it consists of three parts. The outer ear consists of the auricle and the external auditory meatus. The *middle* ear consists of the tympanic membrane and the three ossicles. The *inner* or internal ear consists of the vestibule and the cochlea. This latter contains three canals: the tympanic, vestibular, and cochlear canals.

5. *The Organ of Corti.* It is situated on the basilar membrane. Transverse fibers are stretched across this membrane, containing the ‘hair cells’ which are the receptors.

6. *Sound as Sensation.* There are two main kinds of sound: tones and noises. Sounds have three chief characteristics: *pitch, loudness, and timbre.*

7. *Sound as Vibration.* Physically, sound is a vibration or wave motion in an elastic medium. As such it has ‘frequency’ (vibration rate) and ‘amplitude’ (intensity, energy). *Frequency* determines the pitch; amplitude, the loudness. *Timbre* is the result of the vibrations of a sounding body which vibrates as a whole and in its parts, giving rise to a fundamental and partials (overtones).

Noises consist of a number of fundamentals and their overtones mutually interfering. *Tones* have a definite fundamental. A *musical scale* is a graduated series of tones, ascending or descending in order of pitch according to a specified scheme of their intervals.

8. *Theories of Hearing.* In the *resonance theory* of Helmholtz the transverse fibers of the basilar membrane of the cochlea are assumed to be individually attuned to the frequencies of the sound waves, each to its proper frequency, similar to the strings of a piano. According to the *sound-pattern* theory, the basilar membrane as a whole vibrates in patterns which correspond to the sound patterns. This theory has been modified by *Wever and Bray*, who contend that single nerve fibers need not respond to every successive wave, but only, perhaps, alternately or at certain intervals; this is the *volley theory*. Neither theory seems to be satisfactory in every respect.

Chapter 6

SIGHT

SIGHT IS THE NOBLEST OF THE EXTERNAL SENSES. MORE THAN the others, it brings the mind into cognitional contact with the world. Unaided sight spreads before us in vivid clarity the colors and shapes of objects in our immediate vicinity. Aided by the instrumentalities of telescope and microscope, it penetrates the vast immensity of the starry heavens and the infinitesimal recesses of subvisible bodies. Distances measured in light years and in microns are thus brought within the field of vision.

Sight apparently has the marvelous power of perceiving things at a distance without the necessity of any physical contact. The eye, small though it is in comparison to the objects it beholds, seems capable of encompassing the whole world. Little wonder, then, that physiologists and psychologists have given so much attention to the miracle of sight. Much has been discovered concerning sight through scientific research.

The Organ of Sight

Sight is the sense which is *responsive to the stimuli of radiant energy or light*. The organ of vision is the eye. Its general shape is that of a sphere. It is the only sensory organ with a mechanism which prevents the normal stimulus from affecting the receptors, namely, the eyelid. An ingenious arrangement of muscles enables us to turn the eyeball to the right, the left, up, down, in a circle, and at various directional angles.

The eye itself consists of a number of distinct structures. The outer part of the eyeball is composed of *three layers of tissue*: the sclerotic, the choroid, and the retina. The *sclerotic* is the dense, tough, opaque, white coat or covering which encases the eyeball on the outside, except for the front part (the cornea). The *choroid* is a membrane containing numerous blood vessels and large branched pigment cells, situated next to the sclerotic on the inside of the eyeball. The *retina* is a membrane lining the posterior chamber of the eye next to the choroid; it contains the receptors and is the immediate seat of vision.

At the front of the eyeball the sclerotic is modified into the transparent *cornea*. The cornea is like the segment of a sphere attached to the eyeball. It is transparent, so that light rays can enter the eye. It consists of layers of interlacing fibers, united by a cementing substance. Beneath it is a limpid fluid, called the *aqueous humor*. Just as the cornea is an extension of the sclerotic, the *iris* is an extension of the choroid. It is an opaque, muscular, contractile membrane, perforated by an opening, the *pupil*. The anterior portion of the iris is colored, and this coloring is different in different individuals; the posterior surface is

pigmented, so as to exclude all light except through the pupillary opening. The iris acts as a diaphragm, contracting when light is dim, so that the pupil becomes enlarged, and relaxing when light is strong, so that the pupil becomes smaller. This action is reflex (the 'pupillary reflex') and adjusts the eye automatically to the quantity of light necessary for accurate vision.

The cornea refracts the rays of light, but it is non-adjustive. In order that the rays be refracted according to the distance of the objects seen, a transparent biconvex body, the *crystalline lens*, is suspended by a ring of ligaments immediately behind the iris. It consists of concentric lamellae or plates composed of slender, curved, rod-like cells. The lens is elastic to some extent, so that its curvature can become more spherical or more flattened, depending on the relaxation or contraction of the *ciliary muscles* which control the ligaments holding the lens in place. By means of this varying curvature the rays of light are focused on the retina. The chamber of the eyeball, situated between the lens and the retinal layer, is the *fundus*, and it is filled with a clear, colorless, transparent jelly-like substance, the *vitreous humor*. The latter is enclosed by a membrane, called the *hyaloid membrane*.

The eye, as will be noted, is constructed very much like a photographic camera. It consists of a focusing apparatus (cornea, iris, lens), a dark chamber (fundus, choroid), and a sensitive plate or film (retina).

Fig. 21. Diagram of the Human Eye.

Fig. 22. Cross Section of the Human Retina.

The *retina* is the seat of vision. A number of distinguishable *layers* compose the retina. Beginning with the retinal surface in contact with the vitreous humor and ending with the surface resting on the choroid, these layers succeed one another in the following order: the inner limiting membrane, separating the retina from the vitreous humor; a layer of branches of the optic nerve, together with blood vessels and ganglion cells; the inner reticular layer of fibers; the inner nuclear layer; the outer reticular layer; the outer nuclear layer; the outer limiting membrane; the rods and cones; and, finally, a layer of pigment cells, next to the choroid. The retina forms the innermost lining of the eyeball and is not more than five tenths millimeter in thickness. Toward the center of the posterior surface of the retina is a small yellow spot, called the *macula lutea*, and in it is located the *fovea*, a small depression or shallow pit, which is the area of acute vision. The retinal nerves unite into a bundle and emerge from the retina a short distance from the macula lutea on the nasal side of the eyeball, thereby forming the *blind spot* where no vision is possible.

A *partial decussation* of the optic nerves occurs where the nerves of the two eyes meet. This decussation is termed the *optic chiasm* (from the Greek letter 'chi,' χ , which it resembles). The result of this chiasm or partial decussation is that the nerves of the nasal half of the right eye and of the outer half of the left eye meet and travel to the left hemisphere of the brain, while the nerves of the nasal half of the left eye and of the outer half of the right eye meet and travel to the right hemisphere. Hence, any object to the right of the eyes will throw its image on the left half of the retina of each eye and be perceived by or in the left hemisphere of the cerebral cortex; reversely, the impulses originating from an object to the left of both eyes will travel to the right hemisphere. The terminal branches of the retinal nerves spread out over the entire retina, so that each point of the retina has a nerve. Each nerve goes to a ganglion in the superior colliculus of the midbrain, and from these ganglia nerves proceed to the visual center of the occipital cortex of the cerebrum. In this manner every point of the retina is connected with a corresponding point in the cortex of the brain.

Fig. 23. Diagram of the Optic Chiasm.

While it is commonly stated that the retina (in conjunction, of course, with the brain) is the seat of vision, in the retina itself the *rods* and *cones* are the *receptors*. They are called 'rods' and 'cones' because of their shape, the rods being more long and slender, while the cones are

more short and conical. Contrary to what one might expect, the rods and cones are not placed at the top of the retinal layer next to the vitreous humor, but at the bottom near the choroid. In consequence of this arrangement, light rays must pass through all the retinal layers before reaching these receptors. The function of the rods and cones will be explained presently.

Light Rays as Stimulus

The *stimulus* of sight is *radiant energy*. Ordinarily, the radiant energy of the sun is the stimulus; but star light and artificial lights are also stimuli which normally activate the organ of vision.

Light emanates from luminous bodies in the form of *photons*, and photons are particles or corpuscles approximately the size of electrons. Notwithstanding this fact, light also manifests itself as a form of *electromagnetic wave* propagated through the hypothetical aether. How to harmonize this double phenomenon of light, is one of the great problems of modern physics.¹ Since we are not concerned here with the physical problem of the constitution of light, we will follow the usual procedure of treating light as a wave.

The vibrations of light waves are transverse to the direction of their propagation, and the speed of their transmission is about 186,300 miles per second. The wave lengths of light are measured in millimicrons, i.e., in millionths of a millimeter, of which the symbol is m^{μ} . Not all wave lengths emitted by radiant bodies affect the retina

and stimulate it to vision. Ultraviolet rays are shorter than $400\text{m}\mu$, and ultrared rays are longer than $800\text{m}\mu$, but neither are visible. The range of the visible spectrum lies roughly between wave lengths of $386\text{m}\mu$ and $800\text{m}\mu$. If one passes a ray of sunlight through a prism, one disperses this light into rays according to their wave length and the spectral colors appear: red ($760\text{m}\mu$) is at one end of the spectrum, violet ($400\text{m}\mu$) at the other end, yellow ($580\text{m}\mu$), and green ($530\text{m}\mu$), and blue ($480\text{m}\mu$) in between. Intermediate wave lengths give various shades of these colors. When the stimulus consists of a ray of one wave length, one frequency, it is said to be a *homogeneous ray* of light. Most rays, however, are mixtures of various wave lengths. The white light of the sun has a maximum mixture, as the prismatic colors reveal.

A *physical object is colored*, when it emits, transmits, or reflects all or some of the rays of light. In this sense, a body is 'white,' when it absorbs none of the solar rays but reflects them all diffusely; a body is 'black,' when it absorbs all rays and reflects none; a body is 'blue,' when it absorbs selectively a portion of the rays and diffusely reflects the others, among which the 'blue rays' predominate. The *color of an object*, therefore, from the standpoint of the physicist, is that property of an object, due to its atomic and molecular constitution, which enables it to emit, transmit, or reflect all or some of the rays of light capable of stimulating the retina to sensation. Viewed this way, *objects possess physical color*, irrespective of whether or not they ever affect an organ of sight, because the physicist considers 'color' to be identical with electromagnetic aether

vibrations in so far as they are *capable* of becoming the stimulus activating the retina. Strictly speaking, then, a 'black body' is devoid of all physical color, because it absorbs all light rays, so that no light is emitted or reflected.

Like sound, light waves have *length, frequency, and amplitude*. Differences in these magnitudes bring about differences in the waves. The hue or color depends mainly on the wave length, while brightness or brilliance depends mainly on the amplitude of the wave.

Color as Sensation

The *psychologist* has only a secondary interest in the physical vibrations or light waves which produce vision. His primary interest lies in the *conscious reaction or sensation of sight* evoked by the action of the physical stimulus on the organ of vision. His field of investigation, therefore, is *visual experience*, namely, color as it appears in visual sensation.

All in all, there are more than 30,000 distinguishable colors. Viewed from the standpoint of psychological experience, we have *achromatic* and *chromatic* sensations. In 'achromatic' sensations we experience 'white,' 'black,' and the intermediate 'grays.' There are about 700 different shades of gray between pure white and complete black. They differ from one another in brightness. In 'chromatic' sensations we experience what we ordinarily call 'colors,' namely, blue, green, yellow, red. Although the term 'achromatic' means 'non-colored,' psychologically 'white,' 'gray,' and 'black' are experienced as 'colors,' just as much

as 'blue,' 'green,' etc. We therefore divide visual sensations into experiences of *neutral* (achromatic) and *chromatic* colors.

If we now *classify psychological colors*, we find that we have *six psychologically primary colors*. There are two neutral colors, white and black. The grays are intermediates of white and black. And there are four chromatic colors, red, yellow, green, and blue. All other colors are shades or blends of these four. We have here one of the great differences between physics and psychology. According to physics, neither 'white' nor 'black' is a distinctive color. 'White' has no specific wave length in the spectrum; it is a mixture of the wave lengths of various colors. 'Black' has no wave length at all which could be said to correspond to it. In psychological experience, however, both 'white' and 'black' are colors as distinctive as any of the chromatic colors. 'Black' is not the same as 'colorless' in our experience; distilled water and a clear pane of glass are 'colorless,' but coal and the printed words of this page are decidedly 'colored.'

Chromatic colors have *three attributes* or characteristics:

hue, saturation, and brightness. By *hue* we understand that attribute of a color which we designate by naming it 'red,' 'blue,' etc., distinguishing it thereby from the neutral colors. Although this is a roundabout way of describing a 'hue,' we cannot do better, because the sensation of color is an ultimate datum of experience and such a datum is incapable of strict definition. It is much easier to point to a stick of sealing wax and say "This is red" and to the sky and

say 'That is blue,' and it is this characteristic of 'red' and 'blue,' etc., which we mean by 'hue.' The solar spectrum shows us a series of hues in various shades from violet to red. *Saturation* is the amount of hue present in a given chromatic color. There are, for example, many shades of red, but some shades contain more 'redness' than others; 'pink,' for example, is less saturated than 'cardinal red,' because there is more white and less red in the former than in the latter. We might say that hues, so far as saturation is concerned, run from 'dull' or 'pale' to 'vivid'; 'pink' is a pale or dull red, while 'cardinal' is a vivid red. By *brightness* or *brilliance* we mean that attribute of hues which enable us to place them in a series progressing from 'light' to 'dark.' All hues of the solar spectrum can be placed in such a series, and a series can also be made of any particular hue in its various shades. In the spectrum, for example, yellow is the brightest hue and blue the darkest. In the entire series of green hues, Nile green is very bright and bottle green is very dark. Among the neutral colors, white represents extreme brightness and black extreme darkness; the grays occupy a middle place in brightness between them.

There are a number of *phenomena* in connection with color which deserve special consideration. They give us a better insight into the *psychology of vision* as such. In general, it is true, of course, to say that the sensation of vision depends on the stimulus and varies with the stimulus. Sensation, however, depends also on the *peculiar sensitivity of the receptor organ*, and this vital factor produces phenomena which cannot be explained on the basis of

physical light waves alone. Some of these phenomena will be treated in the sections following.

Rod and Cone Vision

The rods and cones are the *receptor cells* which receive the stimulus of light and react to it. Sight, therefore, has a *duplex apparatus*. According to the theory of *Von Kries*, the rods and cones differ fundamentally in function, and at present no one seriously doubts the truth of the theory. The theory states that the rods are the receptors for *achromatic vision*. The rods are sensitive only to the white-gray-black series; they are insensitive to chromatic colors or hues, such as red, green, etc. On the other hand, the cones are the receptors for *chromatic vision*. They respond to the different wave lengths of light by sensations of chromatic colors or hues (red, yellow, brown, indigo, etc.), and thus are the receptors for what is commonly called 'color vision.

There is good *evidence* in support of the difference between rod and cone vision. The fovea, which is the area of the retina where chromatic vision is most noticeable, contains closely packed cones, but no rods. From the fovea outward, rods begin to occur in the retina and increase in number toward the periphery, while the cones decrease steadily in proportion, until at the extreme periphery the retina contains rods almost exclusively. It is a known fact, however, that the extreme periphery of the retina responds only with sensations of the white-gray-black series but not with sensations of the chromatic- color series. Again, people who are devoid of cones entirely in their retina are totally

color-blind and see all things in the neutral shades of white-gray-black, just as in an ordinary photograph; in order to see objects, these persons must turn their eyes slightly sideways, so as to focus the light away from the fovea to the rods of the periphery. Finally, nocturnal animals, like owls, bats, and others, have eyes which possess mostly rods and few cones, because in the dim night light objects are not seen in chromatic colors but in gray and black or, as it is called, in 'rod-white.'

The *stimulus threshold* is lower for the rods than the cones so that the rods will respond to dim or faint light where the cones of the fovea will not respond at all. The cones are, therefore, 'night blind,' while the rods are able to respond to the dim light of the moon and stars. We can see a faint star in the heavens, not by looking at it directly, but by looking slightly to the right or left of it, because then the light strikes the rods situated in the periphery and away from the central or foveal portion of the retina. A simple *experiment* will show that the rods and cones produce their own particular subjective effect in the perceiver. Place three electric lamps (preferably with carbon filaments) in a row, connected together in one circuit and standing about a yard apart. Decrease the current until the filaments barely glow. Stand in such a position that only the center bulb is seen in the line of direct vision, while the two outer bulbs are seen by oblique vision only. In a darkened room the center bulb will now appear with a red glow, while the two outer bulbs will show the 'rod-white' luminosity. No matter how quickly you shift your gaze from one lamp to the other, only the one directly viewed will be red; the other two will

immediately change to 'rod-white.' You perceive the lamp as 'red' when its rays fall upon the cones, and as neutral 'rod-white' when its rays enter the eyes obliquely and fall upon the rods. The cones, therefore, are the organ of high intensity or *photopic vision*, while the rods are the organ of low intensity or *scotopic vision*. The cones are adapted for daylight and brightness and the rods for twilight and relative darkness.

Color Mixture

By *color mixture* we mean the stimulation of the same retinal spot by light rays of different wave length. These rays may be applied to the retinal spot simultaneously or in rapid succession; the result is the same. Color mixing is important to psychology because of the fact that many diverse physical stimuli will produce the selfsame color sensation, which again proves that there is no point-for-point correspondence between physical stimulus and conscious response. There are *three laws of color mixture*. It should be borne in mind that these laws apply solely to lights, not to pigments.

The First Law. It concerns the *complementary colors* and is formulated in two parts. The *first* part reads: "For every long wave of visible spectrum a definite short wave can be found so that when the two waves are mixed in appropriate proportions, each component of the mixture will neutralize the chromatic effect of the other and the sensation of neutral white will arise." The *second* part reads: "If the relative strength of the two components is not

appropriately adjusted, the neutralization of one component is incomplete and the result of such a mixture is the sensation of an unsaturated color whose tone is determined by that of the stronger component."

This law expresses the general fact that two homogeneous light waves, one of long wave length and one of short wave length, when stimulating the same retinal spot, will not produce the sensation of their respective normal hues, but will produce a sensation of *white* (or gray). The wave lengths which produce the sensation of white are said to be *complementary colors*. The effect does not depend entirely on the specific wave lengths, but depends somewhat on the individual differences of the observers. In his own case, *Helmholtz* determined the complementary colors as follows, the numbers indicating the wave lengths of the homogeneous colors in Angstrom units:

Color + Complementary Color = White

Red (656.2).....Green Blue (492.1)

Orange (607.7).....Blue (489.7)

Gold (585.3).....Blue (485.4)

Gold (573.9).....Blue (482.1)

Yellow (567.1).....Indigo Blue (464.5)

Yellow (564.4).....Indigo Blue (461.8)

Green Yellow (563.6)..Violet (433)

The Second Law. It concerns *intermediate* colors and reads:

“When two waves are combined which separately arouse color sensations whose tones are not complementary to each other, the result of such a mixture is the sensation of an intermediate color.” According to this law, non-complementary pairs of wave lengths, when mixed, will result in color sensations of intermediate hue and brightness. Color mixtures of this type give rise to such colors as orange, yellow-green, green-blue, greenish-yellow, red-yellow, pink, lake, rose, tan, lilac, etc. For example, by mixing red and yellow in different proportions, we obtain vermillion, orange, and gold; red and yellow are non-complementary hues, and their mixture will never give white or gray. By mixing green and red lights we obtain a yellow hue.

The Third Law. It concerns the *substitution* of colors in mixtures containing more than two components and it reads: “If a definite mixture of lights has the color of a definite other light, then this mixture can be substituted for it, whenever this other light is required as a component in some other mixture.” An illustration will make the meaning of this law clearer. Yellow, for example, is one of the spectral colors resulting from a homogeneous ray of light with a wave length of $567\text{m}\mu$. But yellow also results from a definite mixture of red and green lights. Now, yellow and indigo blue lights, when mixed, give white. Instead of homogeneous yellow (y), we can substitute red and green lights ($r + g$) and mix them with indigo blue light ($i.b.$), and by means of this double mixture we obtain white (W). We thus have the formula $(r + g) + i.b. = W$, and that is the same formula as $y + i.b. = W$.

Pigments do not behave like lights in mixing. Yellow and blue pigments give rise to a green color in mixture, but yellow and blue lights give rise to a sensation of white. Yellow pigment absorbs certain wave lengths, including blue; it then reflects diffusely some wave lengths, including green, but the light which is predominantly reflected is yellow. Blue pigment absorbs certain wave lengths, including yellow; it then reflects diffusely some wave lengths, including green, but the light which is predominantly reflected is blue. Then, when blue and yellow pigments are mixed, the blue pigment absorbs the yellow, and the yellow pigment absorbs the blue; the green rays, however, are still reflected by both, and so the mixture of both pigments results in green color. It will thus be seen that the mixture of *lights* is a matter of *addition* of wave-length stimuli, while the mixture of *pigments* is a matter of *subtraction* or double absorption of wave-length stimuli. Hence the difference.

Color Contrast

A psychological phenomenon somewhat similar to color mixing is that of color contrast. By color contrast we mean the *difference in the appearance of colors* brought about by the stimulation of adjacent sets of rods and cones in the retina. When one set of rods and cones is stimulated by certain kinds and amounts of lights or colors and the adjacent set of rods and cones is stimulated by different kinds and amounts of lights or colors, then these different stimulations bring about a condition in which the affected

sets mutually modify each other to such an extent that the colors change their appearance in some measure. These changes in appearance are sometimes quite pronounced. The effect of color contrast seems to be mainly the result of *physiological inhibition*. The stimulation of one area of the retina inhibits, either partially or completely, the effect produced in the other, and the result is a change in the appearance of a definite color.

The student can observe the effects of *simultaneous contrast* by means of a simple experiment. Take sheets of colored paper of as many hues as you can procure — white, black, red, yellow, green, blue, and intermediate colors. From each sheet cut out a piece two inches square, to be used as a background. Then cut out small pieces about half an inch square from each sheet, so that you will have a small piece of the same color to place in the center of each background. Now place a small piece of yellow paper against the larger background of white, black, red, blue, etc., preferably in the center of the background. Arrange the backgrounds with the yellow pieces in a series, side by side, on a table in good light, and compare the yellow pieces one with the other. Note the *different shades* of yellow which now appear against the various backgrounds. Do the same with pieces of blue, green, etc., placing them on the same backgrounds. The apparent change in color for pieces taken from the same sheet of paper is rather remarkable. Though they all have the same color in the sense that they reflect the same wave length, the psychological effect, due to simultaneous contrast in adjacent retinal areas, has

changed the sensation of color considerably for the individual pieces.

Against a green background gray appears tinged with red, blue seems purplish, and yellow becomes more like orange. The laws of color mixture apply here, so that contrast effects tend toward the complementary colors of the contrasting colors; a green background, for example, induces a sensation of red in the color placed within its field. That is why it is unwise to select colored fabrics under artificial light; artificial light is usually yellowish and that produces color contrast.

Afterimages

Adaptation is a common phenomenon of vision. Prolonged stimulation of the same retinal area by a uniform stimulus decreases its effectiveness and makes this area more sensitive to the stimulus of the opposite color. *Successive contrast* results.

One type of successive contrast is the *afterimage*. Afterimages are sensations occurring after the stimuli causing them have ceased. They are of two kinds: negative and positive. A visual afterimage is *negative* or *complementary*, when a dark image is replaced by a light image, or a light by a dark, or the color of the original sensation by its complementary color. A visual afterimage is *positive*, when it preserves the color or shade of the original sensation.

Afterimages or after-sensations occur because it takes a certain amount of time for the visual apparatus to reach the

height of its response to the stimulus, and it also takes some time for the apparatus to lose the effect of the stimulus. In consequence of this *after-lag* the response continues for a time after the stimulus has ceased. If someone swings a torch in a circle at night, the after-lag of the response produces the sensation of a fiery ring. Motion pictures make the impression of continuous action, although there is a lightless interval between the individual pictures thrown on the screen, because the response of the retina, due to after-lag, persists after the picture has been removed from the screen and thus bridges the gap of the dark interval between one picture and another; if the dark interval is too long, we observe a flicker. We notice the same phenomenon in an electric lamp using alternating current; the light appears constant and continuous. In such instances we still have the *original response*, not an afterimage. This after-lag of the original response does not last longer than half a second after the stimulus has ceased. That a certain *aftereffect* still persists in the retina after the original response has faded out, is observed in the fact that afterimages can be seen after a blank interval following the original response and its after-lag.

The student can easily demonstrate to himself the existence of positive and negative afterimages. Place a sheet of white paper used for typewriting and a piece of black or very dark cloth of about the same size side by side on a table. Look for a second or two directly at an exposed electric lamp, one with clear glass. Then turn your eyes to the paper and to the dark cloth, blinking the eyelids at the same time. You will see the outline of the filament loop of

the lamp, now bright like the original (positive afterimage), now in its complementary color (negative afterimage). On a dark field the image will in all probability be positive, if you look at the field without blinking, and on a light field it is likely to be negative; the effect, however, depends on a number of circumstances. After a while these afterimages become weaker and weaker and then disappear entirely. Afterimages can, of course, be produced in many ways. A simple method is to look at a black or white or colored object with a fixed gaze for about half a minute and then turn the eyes upon a background of medium gray, and a negative afterimage will appear. These images are *subjective* in character, because they follow the movement of the eyes in any direction, after the eyes have ceased looking at the original object. As a rule, we do not see afterimages in the daytime, because bright light blots them out; however, if we look at the setting sun and then look at other objects with a flat surface, we obtain afterimages of the sun, because the sun is brighter than these surfaces.

Color Blindness

Color blindness is another interesting phenomenon of vision. By *color blindness* we understand the partial or total inability to distinguish or recognize chromatic colors. It is an abnormality of vision in which certain colors drop out of the spectrum for the individual observer or all things are seen in neutral colors. Color blindness is adjudged an 'abnormal' condition in the visual mechanism because

ninety-five per cent of persons see all the chromatic colors of the spectrum.

Color blindness assumes different forms. According to physics, *there are three primary colors*: red, green, and blue. The proper mixture of these will produce any hue. The ability to see these primaries equally well constitutes normal vision and is termed *trichromatism* (three-color vision); a normal person is said to be a 'trichromat.'

Partial color blindness is dichromatism, and it exists in two forms: red-green blindness, or blue-yellow blindness. In red-green blindness these two colors appear as gray. This type of color blindness may follow one of two patterns. It may be red blindness, in which the brightest part of the spectrum is in the normal yellow-green, and the red end of the spectrum is invisible; this is called *protanopia*. Or it may be green blindness, in which case the brightest part of the spectrum is the normal yellow; this is *deutanopia*. In *blue-yellow* blindness, the second form of dichromatism, blue and yellow appear gray, while red and green, or blue-green, are distinguished; this type is termed *tritanopia*. About four per cent of males are protanopes or deutanopes; color blindness is seldom found among women. Tritanopia, or blue-yellow blindness, is extremely rare. Much of the data concerning partial color blindness have been gathered from the experiences of persons who had trichromatic vision and then, through disease or injury, had become color-blind. One or the other case is on record where a person was normal in one eye and colorblind in the other.

Total color blindness, or *monochromatism*, is relatively rare. Persons afflicted with this form of color blindness are

unable to see any colors of the spectrum; they see all objects in neutral tones of white-gray- black, as in an ordinary photograph. Though their vision is deprived of all chromatic color perception, they are able to distinguish differences in brightness.

Color weakness is not color blindness. Persons who are color weak see all chromatic colors and can distinguish them, but some colors need a *stronger* stimulus than others in order to be seen. Red and green light, for example, produce the sensation of yellow, when properly mixed; but a red-weak person needs more red, and a green-weak person needs more green, in order to obtain the yellow which a normal person sees.

Since the receptors of chromatic color vision are the cones of the retina, color blindness and also color weakness presupposes some defect in the cones. And since in dichromatism the vision of one or the other color is missing, while vision for the rest is unimpaired, one must assume that the defect responsible for color blindness is present in practically all the cones of the eye or eyes. Just what this defect could be, is difficult to say. An adequate explanation of color blindness is a crucial test for a good theory of vision.

Binocular Vision

Man's two eyes are placed in such a position that both look forward. The object seen is observed from two divergent angles; and thus the field for each eye is slightly different, and the fovea of one eye receives an optical image which

differs to some extent from that of the other. It would seem that man should see two distinct fields and two distinct objects. When normal eyes, however, are directed toward an object, they see but a *single object and a single field*. What is the explanation?

There is a *correspondence* between the *retinal points* of one eye and those of the other. The *fovea*, where focusing occurs, is a relatively small area, and it is assumed that here the correspondence is rather close. Due to the decussation of the optic nerves, the foveal points are connected with each hemisphere of the brain, so that the two foveas act as a single organ of vision. The result is a *single cortical response* to the two overlapping retinal fields, termed *binocular fusion*. Fusion occurs only when the rays of the field or of an object are focused on the foveas in a practically identical manner.

We can and do see *double images* of the same field or object when the two foveas are out of alignment. With both eyes open, look at some object, say a book, and then press a finger against one eyeball, thereby pushing this eyeball out of its normal position with respect to the other; you will see two images of the book, one stationary (in the stationary eye) and one moving (in the eye moving under the pressure of the finger). Even in ordinary vision we see double images. Focus your eyes on an object about five or six feet away, and then place your extended index finger directly in the line of vision about six inches in front of your eyes while they remain focused on the distant object; you will have a single image of the distant object, but a double image of your finger, and you will be able to see the distant object (or

field) *through* the images of your finger. If you focus your eyes on a near object, the distant object will appear double. Be sure that you do not shift the focus of your eye in this experiment. Ordinarily, of course, we never notice these double images, although they are always present, because we concentrate our attention upon the object in focus and neglect the rest of the field. It is only at the focal point of the fovea that the two optical images are practically identical and are thus capable of fusion. In the outlying areas of the retina the rays of light will not converge to a point, but cross, and throw the image of the object or field on different retinal areas, thus producing the vision of a double object or field.

Binocular rivalry occurs, when each eye, separately and simultaneously, sees colors or objects or figures which are very different in appearance. Under such conditions, at first there is a response only to one field: the image of one field is seen, that of the other is suppressed and invisible. Then a shift occurs, in which the latter field, at first invisible, now become visible. After an interval the fields are again reversed, and this alternation of the two fields continues back and forth. It is as if a 'rivalry' existed between the two eyes. When complementary colors are used in these experiments, some observers experience only a rivalry; others, however, experience *psychological fusion* according to the laws of color mixture. In the case of fusion of complementary colors, this fusion cannot occur in the retinas themselves, because each retina is stimulated by a single wave length of light. The fusion can only occur in the midbrain or in the cortex; and in all probability the

response is in the cortex of the cerebrum. If this interpretation is correct, it is an indication that the cortical response has more to do with actual color sensation and general vision than is usually supposed. The shift of fields in binocular rivalry seems to receive its explanation in *adaptation* or *fatigue*. The neural mechanism responding to the one field gradually suffers fatigue, whereupon the other field forces itself into the foreground, only to be replaced after a while by the first field; the process repeats itself alternately through fatigue and recuperation.

Behaviorism and Color Vision

It is an axiom of *behaviorism* that an *exact correlation* exists between *stimulus* and *response*; the response is the exact physiological counterpart of the stimulus. If we know the stimulus (cause), we also know what response (effect) will follow; and if we know the response (effect), we also know the stimulus (cause) which produced it. Applied to physiological optics, this axiom means that, if we know the wave length, amplitude, and form of the light wave, we can predict what sensation of color will ensue. Facts, however, show that the *behaviourists are in error*.

Different stimuli produce the same sensation. Given certain stimuli of light waves, we cannot predict automatically the sensation which will follow; introspection shows that the response may be different from what the behavioristic axiom would indicate. Mixing wave lengths 656 and 567 (red and yellow) should give a blend of the two, namely 612 (orange); and it does. Then mixing yellow

and indigo-blue should give a blend of these two, and so should the mixing of red and green-blue; but it does not, because these are complementary colors, and complementary colors give white (or gray), which has no resemblance to the colors which act as stimulus. All complementary colors act in this manner.

Simultaneous contrast shows that the sensations of color change, even though the kind and amount of wave lengths emitted or reflected to the retina remain unchanged. Hence, from the nature of the stimulus we cannot predict the character of the sensation.

The *sensation of black*, which is just as characteristic as white or blue, etc., should be impossible in the theory of behaviorism, because no light waves reach the retina from a 'black' object. 'Black' is an indirect effect of light, arising under simultaneous or successive contrast; but it is real enough, as we can readily observe by reading the print of a book. The mere absence of the stimulus, therefore, will not enable the behaviorists to account for the sensation of 'black.'

The *negative afterimage* are genuine phenomena of mental life; yet, since they are 'negative' in character, no objective method of behaviorism can detect their existence. They are perceivable by no one but the sentient individual, and he alone can describe their properties through introspection.

Visual Space

What we see in vision is not the retinal image, nor the electromagnetic waves of light, nor color mixing, nor simply patches of color. These realities, of course, are present and play their respective parts in vision and without them vision would be impossible. What we actually see in vision are *objects, things*: human beings, animals, plants, buildings, vehicles, fields, clouds, sky, etc. When we designate the objects of vision in this fashion, we are not speaking of visual sensations but of *visual perceptions*.

We apparently see things in definite *places*; they are a certain *distance* away, both in relation to ourselves and to other things; they have a definite *size* and *shape*; they are composed of *parts* spread out in the *three spatial dimensions* of length, height, and depth. In other words, we have a perception of visual space in three dimensions. If we inquire into *how* this perception is acquired, we are confronted with a rather complicated problem.

Colored surface in two dimensions is an immediate visual experience. Any seen object or patch of color shows that it is spread out in height and length; we cannot see a mathematical point. In any seen object or patch of color, we can intuitively distinguish 'right' and 'left,' 'up' and 'down'; consequently, we distinguish concrete parts of surfaces. We cannot see an object or patch of color, if they lie within the bounds of the visual field, without seeing their general shape; colored surfaces have limits of extension which involve shape, and 'shape' or 'form' is thus concretely given with the vision of colored surfaces, as anyone can observe by looking at a landscape or series of buildings. Even relative size is concretely given with colored surfaces;

looking at an archery target, we see that the outer rings are relatively larger than the inner rings.

Depth in space, the third dimension, is not an immediate experience, but a matter of perception and judgment. We have become so accustomed to interpret the visual image in three dimensions, it seems that depth in space is also a datum of immediate experience. Distance and depth are rather a matter of *interpretative judgment*, and that is acquired through learning.

Merely looking at the heavens gives us no indication of the absolute size and distance of the sun, moon, and stars. History proves this; it is only through astronomical calculations that these things are now known to us. Perspective seemingly enables us to observe depth in space directly; that this judgment is erroneous, is clearly shown in stereopticon views, where flat pictures have apparent depth. The futile graspings of infants at objects which they see indicates that distance in space and absolute size are not directly given in visual images. More valuable evidence is derived from the experiences of persons who, blind from birth, had received their sight in later years, so that they were able to give a rational account of their new experiences. There was no experience of depth in space, and everything was seen in a flat side-by-sideness in two dimensions.

HOW DO WE LEARN TO INTERPRET OUR VISUAL IMAGES AS TO *DEPTH* and *distance* in space? Why are we so certain that there is a

third dimension? A number of factors are involved in this process of interpretation.

In this respect the *tactual sense* is a great aid to sight. By means of the tactual sense, we experience *double contact* in our own body; that is to say, by passing our hands over our body, a contact is established between the hands and the body, hands and body both experiencing sensations of touch. In this manner we soon learn the general contour of our body, the relative position of the various members, and their relative size with respect to one another. We also learn that the various members are distinct from one another; hand, leg, foot, arm, trunk, head, etc., are not the same, and yet they are all parts of our own organism and belong to our body. When we grasp a pencil or an apple we obtain a rough estimate of size, shape, etc.; most of all, however, we perceive that they do not belong to our being, but are totally different from our self. We have the same experience when we touch a tree, a desk, a building, or some other person. By *combining sight and touch* we learn to distinguish ourselves and other beings, some of which are similar to our being (other persons) and others dissimilar (pencil, apple, tree, building, etc.).

From here to the *perception of depth* in space is but a short step in experimental learning. Through contact with an object by the hand or body, we experience pressure and kinesthetic sensations; through sight we see the contact made. We notice, however, that we do not always obtain sensations of contact, even though in the visual image the hand seems to touch the object. We then stretch out the hand to make contact; even this does not suffice at times,

and then we walk toward the object. When we finally reach the object and touch it, our visual and tactual images again coincide. Our body thereby becomes a standard of measurement, and we thus learn two very important facts: *depth and distance in space and the measurement of this depth and distance in space* in terms of a standard of measurement. We now realize through progressive experience that some objects are near and some are far.

Having established the fact of depth and distance through the combined data of sight and touch, we begin to observe *many criteria in the visual image* itself which can be utilized effectively in gauging the size and distance of objects in space.

Light and shadow are criteria of distance and depth in space. There are 'cast shadows' and 'attached shadows.' When a light is thrown onto an object, the object casts a shadow onto the ground or onto another object. The light on a contoured object, i.e., an object not entirely flat, does not cover the object evenly; some parts are highlighted, and others are shaded or in shadow, and this type of shadow appears attached to the object itself. If we know the source and direction of the light, we can form a fairly accurate estimate of depth and distance. The cast shadows reveal the relative distances in space between one object and another, while the attached shadows reveal the three dimensions of a particular object taken alone.

Perspective is another criterion. 'Linear perspective' reveals distance by the apparent reduction in the size of known objects. A horse, a man, and an automobile, for example, seem to become larger as they approach, and

smaller as they go away from us; we can gauge the distance in space by the apparent size. In 'detail perspective,' an object loses more and more of its distinctness in line and shape as the distance from the observer increases. Knowing these items from close observation, their progressive diminution in distinctness becomes a criterion of distance. Due to 'aerial perspective,' it is noticeable that familiar objects lose color tone, vividness, and brightness as they recede into the distance. 'Movement perspective' is another criterion. Watch a speedy airplane close overhead and note how fast it cuts through space; but as it circles around in the distance, it almost seems to stand still, although its speed is still the same. These various types of perspective, therefore, are cues to distance and depth in space.

In binocular vision of a nearby object, the *angular difference* of the two overlapping optical fields also reveals depth in space with regards to the shape of the object, because we thereby see 'around the corner' of an object. The stereoscope is based on this fact.

Another factor which assists us in gauging distance is the *focusing of the eyes* by means of the muscles of the eyes. When we look at an object which is very close, it appears blurred in outline and detail, and the muscles are strained in the attempt to make the eyes converge sufficiently for accurate focusing. When we look at a remote object, convergence and muscular strain are absent.

Experience teaches us to make use of a *combination of tactile and visual cues* in order to estimate the relative size of objects and their distance and depth in space. Training and learning, together with association, enable us to

interpret these cues so proficiently that we have the impression that the perception of the third dimension is directly given in our visual image.

TWO OPPOSING THEORIES OF VISUAL SPACE DESERVE MENTION: *nativism* and *empiricism*. The nativists claim that our perceptions of space are the result of a native or constitutional property of vision itself, independent of learning and interpretation. The empiricists claim that our perceptions of space are entirely and exclusively a matter of experiential education; due to the kinesthetic sensations accompanying the movements of the eye in vision, we obtain cues or 'local signs' which enable us to pass a judgment on the direction and distance of objects in space.

The *nativists* advance a number of facts in support of their theory. Spatial dimensions are given directly in the perception of colored surfaces. Chicks just out of the egg pick at grain particles with unerring accuracy and follow the movements of a worm or insect without difficulty. Similar incidents are reported about other animals, and they seem to indicate a congenital faculty of space perception. Examples from animal life, however, are inconclusive, because it could be that the sense of smell has more to do with their actions than sight. While the nativists are correct in stating that spatial dimensions are necessarily involved in colored surfaces, it does not follow that the perception of the third dimension is also an immediate datum of visual experience; the perception of the third dimension, as we have shown, is rather a matter of

interpretation based on the sense of touch and on various cues of the visual image.

The *empiricists* also advance certain facts in support of their view. They refer particularly to the cases where persons, blind from birth, have received sight. Cheselden, Wardrop, and Franz reported such cases more than a century ago, and many cases of a similar kind have been described since. Such persons have no perception of distance or depth in space and must learn to interpret their visual images. They have, however, an immediate vision of the two dimensions of length and height. It is the contention of the empiricists that the sense of sight has no native capacity of recognizing extension in any manner. In order to see a circle or triangle, the eye must follow the lines of these figures, and the eye itself must move in the form of a circle or triangle. From these muscular sensations, through experience and association, we gradually acquire the notion of extension and three-dimensional space. These muscular movements of the eyes thus become the 'local signs' whereby we judge distance. Lotze (1817—1881) was a prominent exponent of the 'local sign' theory. Empiricists are wrong in attributing our judgments about dimensions to the muscular sensations of the eye following the lines of figures, etc. Were their contention correct, we would have no notion what a circle, triangle, or other mathematical figure is like, because photographic reproductions of the eye movements show they are jerky and irregular and never describe anything like the smooth lines observed in the contour of any object or figure. Eye movements form one of the criteria of distance and size, but they play only a

minor part; criteria present in the visual image itself, as mentioned above, play the major part in space perception.

These facts concerning vision, furnished by the physicists, physiologists, and psychologists, are very informative. The *fundamental purpose* of the sense of sight, as of the other external senses, is the *adjustment* of the organism to its surroundings. As a living being living in a world of manifold objects, man must be able to find his way about among them. All the senses serve as channels of information regarding these objects, so that man can protect, preserve, and develop his being as an *integral organism*.

One fact stands out prominently, as we look back over these various senses: Sense function is a type of activity far superior to that of physical or chemical substances, and sense function cannot be explained in terms of physical or chemical action and reaction.

The information assembled by the external senses is passed on to the internal senses; these must now be examined.

Summary of Chapter VI

More than any other sense, sight brings the mind into cognitional contact with the world.

1. *The Organ of Sight.* It is the eye. The eye consists of a number of distinct parts: the sclerotic, the choroid, the retina, the cornea, the iris, the lens, the aqueous and vitreous humors. The *retina*, which is the seat of vision, is composed of various layers of tissue. Its rods and cones are the receptors.

2. *Light Rays as Stimulus.* Light appears as photons and also as electromagnetic waves. The range of the visible spectrum lies between wave lengths of $386\text{m}\mu$ and $800\text{m}\mu$. Light waves have length, frequency, and amplitude.

3. *Color as Sensation.* In achromatic sensations we experience white, black, and gray; in *chromatic* sensations, red, blue, green, yellow, and intermediate hues. There are *six psychological* primaries: white, black, red, green, yellow, and blue. Chromatic colors have three attributes: hue, saturation, and brightness.

4. *Rod and Cone Vision.* The rods are the receptors for achromatic, low intensity, scotopic vision; the cones are the receptors for chromatic, high intensity, photopic vision. The organ of sight, therefore, is a duplex apparatus.

5. *Color Mixture.* By this we mean the stimulation of the same retinal spot by light rays of different wave length. There are *three laws* of color mixture. The first concerns complementary colors; the second concerns intermediate

colors; the third concerns the substitution of colors in mixtures containing more than two colors.

6. *Color Contrast*. By this is meant the difference in the appearance of colors brought about by the stimulation of adjacent sets of rod and cones. Contrast seems to be mainly the result of partial or complete physiological *inhibition*. *Simultaneous* contrast can be observed by placing a piece of colored paper against variously colored backgrounds.

7. *Afterimages*. Afterimages are sensations occurring after the stimuli causing them have ceased. They are *negative* or *complementary*, when a dark image is replaced by a light image, or a light by a dark, or the color of the original sensation by its complementary color. They are *positive*, when they preserve the color or shade of the original sensation. Afterimages are subjective.

8. *Color Blindness*. This is the partial or total inability to distinguish or recognize chromatic colors. *Dichromatism* or *partial* color blindness exists in two forms: red-green and blue-yellow blindness. In *monochromatism* or *total* color blindness a person sees all things in the neutral colors of white-gray-black.

9. *Binocular Vision*. The optical fields of both eyes, though slightly different, are seen as a *single field*, due to binocular fusion in consequence of a single cortical response. When the two fields are focused on the fovea in a practically identical manner, fusion occurs; otherwise we see double images. Binocular *rivalry* occurs, when each eye, separately and simultaneously, see colors or objects or figures very different in appearance. When complementary

colors are used, *psychological fusion* may occur according to the laws of color mixture.

10. *Behaviorism and Color Vision*. In accordance with this theory, an exact correlation must exist between stimulus and response. Such an exact correlation does not exist in color vision. Different stimuli produce the same sensation. In simultaneous contrast the sensations of color change, though the kind and amount of wave lengths remain unchanged. The sensation of black is not properly accounted for. Afterimages are subjective in character.

11. *Visual Space*. Colored surface in two dimensions, length and height, is an immediate visual experience; visual experience also includes the intuitive distinction of concrete parts, shape, and relative size. *Depth in space*, or the third dimension, is a matter of perception and judgment. The combination of *touch* and *sight* assists us in interpreting the visual image with respect to depth in space. Thereupon certain *criteria* in the visual image enable us to gauge depth: light and shadow, perspective, angular difference of the optical fields in binocular vision, and the muscular movements of the eyes in focusing.

Nativism attributes perception of space to a native or constitutional property of vision itself. The theory, however, is wrong in including the direct perception of the third dimension, depth in space. *Empiricism* attributes it entirely and exclusively to experiential education, in which the kinesthetic sensations of eye movements furnish us with 'local signs.' This theory overlooks the fact that the visual image itself furnishes criteria of visual space and that the vision of colored surfaces gives two dimensions immediately.

Chapter 7

CENTRAL OR SYNTHETIC SENSE

[FORMERLY KNOWN AS THE 'COMMON SENSE',
ED.]

INFORMATION CONCERNING CONDITIONS IN MAN'S OWN organism and in the outside world comes to the mind through the channels of the external senses — sight, hearing, taste, smell, and the somesthetic senses. This information comes piecemeal. Each sense resembles a brook, and each item of sensation resembles a drop of water carrying a bit of information in solution, and through these diverse sources an enormous amount of information flows into the common reservoir of the brain.

These bits of information do not remain isolated, nor do they mingle indiscriminately into a jumbled mass of heterogeneous items. They are analyzed, sifted, sorted, arranged, and combined into meaningful wholes; they are stored away, capable of being recalled for future use, ready to be compared and combined with further information received from the vital sources of the senses as time goes on. This process of elaboration is carried out by the *internal senses* — the *central sense*, *imagination*, *sensory memory*, and *instinct*. These will now be discussed.

The Central Sense

We may define the *central sense* as the mental *power to consciously perceive, distinguish, and synthesize the objects and operations of the presently active external senses*. From Aristotle down through the Middle Ages and up to our own day, this power has been termed the *common sense* (*sensus communis*). While the name is accurate enough in its technical meaning, the English language unfortunately uses the expression 'common sense' more frequently to designate things totally different. Sometimes 'common sense' is used to mean plain good judgment; again it is used to mean the intuitive judgment of mankind relative to certain fundamental principles; and it is also used to designate the unscientific and unreflective opinions of common people who lack an extensive education. Because of these various meanings, it seems unwise to apply the term 'common sense' to the internal sense in question. T. V. Moore employs the term *synthetic sense*. We prefer the term *central sense*, because it is general enough to include all the functions proper to this sense, without any danger of confusing it with other mental powers. In as much, however, as Moore's term is apt and expressive, it may be advisable to speak of this power either as the 'central' or 'synthetic sense.'

The central or synthetic sense has a *double function*. When the external senses react to a stimulus, so that the eye sees and the ear hears, etc., the central sense perceives and distinguishes the various sense qualities presented, combines them, and refers them to the *one object* from

which the stimuli originate. This is the objective phase of the function of the central sense. There is, however, also a subjective phase to its function. By means of the central sense we become *aware of the acts of sensation* present in the various external senses, such as the act of seeing and the act of hearing, etc.; and we also become aware of their differences as acts of sensations, so that we know that the act of seeing is not the act of hearing, etc. Viewed from the standpoint of this latter function, the central or synthetic sense is termed *sensory consciousness*.

Existence of the Central Sense

Introspection proves that we have the ability to *distinguish* between the *qualities* perceived by the various external senses. The eye, of course, can distinguish between white and black, between red and green; taste can distinguish between bitter and sour and sweet and salty; smell can distinguish between fruity and fragrant and fetid odors; hearing can distinguish between high and low notes, between a cacophonous noise and a clear tone; and the somesthetic senses can distinguish between the different sense qualities in their particular field. But one sense knows nothing of what is registered by another sense: sight knows nothing of sound, hearing knows nothing of color or flavor or odor or cold or pain, etc. We distinguish, however, between these various sense qualities and the sensations they produce in us. For example, we distinguish between the whiteness, roughness, and sweetness of sugar; between the shape, the tone, and the touch of a violin; between the

blackness, the odor, and the disagreeable taste of tar; between the sharpness, the temperature of a needle, and the pain caused by its puncture, and so on.

Introspection also proves that we *combine* these different sense qualities and refer them to the *same object*. I take a certain thing between my fingers, and it is hard and square to the touch; I look at it and see that it is white; I taste it, and it is sweet. The fingers know nothing of its color or taste; the eye knows nothing of its hardness or taste; the tongue knows nothing of its hardness or color. Yet I make a synthesis of these irreducible qualities, refer them to the same object, and call it 'sugar.' I look at my desk and see a pencil; it is yellow and slender, and I take it and strike it against the desk, hearing a sharp sound. These are sensations of sight, touch, and hearing. I refer them all to the one same pencil, and I perceive that they all belong together, simultaneously, to the same object. What makes the synthesis of these heterogeneous items? Since the single senses respond only to their own stimuli, no single external sense nor combination of senses can effect the synthesis. There must exist, therefore, a central sense to which the single senses relay their information; this *central sense*, upon receipt of the data of the separate senses, distinguishes between them, combines them, and then refers them to the one concrete object from which the various stimuli originate.

That this analysis and synthesis of sensations and their objects is not an intellectual operation, but the activity of a sensory power, is shown by the fact that *brutes possess this ability*. Consider the actions of a dog. Suppose the dog is in

one room, and his master is in the adjoining room behind the closed door. If the master calls the dog by name, the dog will prick up his ears and listen; he recognizes his master's voice. Not seeing his master, he runs about; coming to the door, he sniffs and recognizes the odor peculiar to his master. If the master now opens the door, the dog runs to him without hesitation, even if other persons are also present. The dog knows that he hears his master, but he also knows that he does not see him; he recognizes the fact that the sound and odor are those of his master, but he also knows that he lacks the sight of his master; and when he sees him, he combines sound and odor and sight and refers them to the same object, his master. The dog, therefore, makes a concrete distinction between the various sensations and their objects and synthesizes them into a concrete whole. A lion does not bite so eagerly into the neck of a zebra because the zebra has a striped hide or emits a certain odor or utters a peculiar sound. The lion kills the zebra because the zebra tastes so delicious. But the lion knows that objects of such a shape and color, emitting such an odor, and uttering such a sound, have a delicious flavor. The lion thus distinguishes between these sensations and the sense qualities and refers them all to one object. Such examples could be multiplied indefinitely. They show that animals possess a central or synthetic sense.

IN A SIMILAR MANNER, IT CAN BE SHOWN THAT MEN AND BRUTES possess sensory consciousness, so that they are aware of

their sensations and of the sense qualities present in the sensations.

If I take a bell in my hand and ring it, I not only see its shape and color, perceive its hardness and temperature, and hear the sound of its ringing, but I am aware of the fact that I see the shape and color, perceive its hardness and temperature, and hear its sound. I have such an experience every time I pay attention to my senses and their operations and attempt to discover, for example, how acute my hearing is by listening to the tick of a watch, how sharp my eyesight is by reading a distant sign, how delicate my touch is by fingering weights when blindfolded, etc. In such cases I not only have sensations but 'become aware of them. It is obvious, however, that the eye is not conscious of its seeing, nor the ear of its hearing, nor the finger of its touching, etc. Much less can the eye be conscious of the hearing of the ear or of the touching of the fingers; and the same must be said of each of the external senses with respect to the sensations of the others. Still, the awareness of the operations and qualities present in the senses, singly and conjointly, is a fact. Since this awareness cannot be attributed to the external senses themselves, we must admit the presence of a central or synthetic sense which is conscious of these senses, their operations and sense objects.

Brutes, too, possess sensory consciousness. They seek to alleviate pain, hunger, thirst, sex urge, etc. If they were not conscious of these things, how could they seek to alleviate them? They look at a wounded foot and lick it; if they were not conscious of the pain, they would not act in this manner.

They manifest signs of pleasure, fear, and anger. Scratch a dog under the chin, or stroke the back of a cat; they give every indication of pleasure and of being aware of the pleasurable feeling. When the master approaches the dog with a whip, the dog slinks away or crouches at the feet of the master; he shows fear of the whipping and is conscious of the anticipated pain to be received from the blow. When the dog and the cat collide, they jump apart, face each other, the dog barking and the cat spitting, ready to fight; they are angry, and they are conscious of the fact that they stand in the face of an attacking foe. None of these actions have any meaning except under the supposition that animals are conscious of objects and of their own sensory reactions in a concrete manner.

Animals exhibit curiosity in their surroundings, and that presupposes consciousness. One of the most comical scenes to witness is the first acquaintance of a dog with a live frog. Curiosity prompts the dog to investigate this object. He walks up to the frog, inquisitive but cautious, eyes it uncertainly, and then sniffs it. When the frog, frightened, leaps through the air, the dog is visibly perturbed, jumps away, stops, stares at the strange creature, hesitates, barks, quiets down, and then, perhaps, approaches it again with the slowness and deliberation of a very mystified observer. Who would say that he is not conscious of the frog and his own perceptions in its presence? Or, if a squirrel is near, toss a piece of candy on the ground, and watch its antics. Curiosity urges the squirrel to examine the object, while fear of the human being holds it in check. It approaches stealthily, stops, flashes its tail, and then scampers away in

fright. The action is repeated from a different angle of approach a number of times, but every time the squirrel comes a trifle closer, until at last it can smell the candy and give it a tentative nibble; if the taste is agreeable, it will grab the candy in its paws, put it between its jaws, and rush away to enjoy the morsel in safety and leisure. The squirrel most assuredly is conscious of the object perceived and of its acts of perception. Animals show curiosity by turning their head to hear better, by looking fixedly at objects to see better, by approaching objects to smell them better, and so forth. Such actions show that they are conscious of the sensations present in their sense organs and of the objects presented by them.

The mere fact that men and brutes have *different senses* makes a central or synthetic sense a necessity, for they would be useless without it. It would be useless for an animal, whether man or brute, to see food, if the animal were not conscious that it is food. The animal could not strive to relieve the sensation of hunger by taking food, if it did not experience hunger consciously as its own hunger. It is obvious that men and brutes do not experience sensations as detached, isolated, unconsciously received processes, but are aware of the presence of these processes as their own in a concrete sensory manner. The fact, however, necessitates a central or synthetic sense capable of distinguishing and synthesizing the data presented by the separate external senses, because otherwise there would be no common bond which would enable us to compare, distinguish, and unite them into concrete wholes.

It is precisely because of this common bond that the philosophers of old termed this sense the 'common sense.'

Gestalt and Synthetic Sense

The *associationism* of Hume, which has dominated modern psychology to a great extent, was frankly sensationalistic. According to Hume, there are just two fundamental elements which enter into the fabric of human knowledge, 'impressions' and 'ideas'; translated into the terms of modern psychology, these are 'sensations' and 'mental images.' The 'ideas' (images) are but faint replicas of 'impressions' (sensations), and these are all we can and do know. They are simple, discrete components which are combined and recombined in various ways according to the laws of association. Hume insisted that they are isolated, discrete 'existences' or elements, and the mind cannot perceive any connection between them, nor can it combine them into higher units or organized wholes; this theory follows logically from his doctrine that the mind of man is not a distinct entity but merely "a heap of perceptions."

The philosophy of Gestalt (a German word for 'form' or 'shape' or 'configuration') is in opposition to this 'atomistic' concept of Hume and his followers. The more recent School of Gestalt was founded by M. Wertheimer, K. Koffka, and W. Köhler about the year 1912. For the isolated, discrete psychic elements of sensationalism and associationism they substituted 'organized wholes,' 'configuration,' 'Gestalt.' In this view the whole is not a mere sum of the discrete parts, but something over and above the sum of the parts; the

whole is prior to its component parts; the parts derived their character from the whole, not the whole from the parts. Wertheimer expresses the essence of the Gestalt theory in this manner: "There are wholes, the behavior of which is not determined by that of their individual elements, but where the part-processes are themselves determined by the intrinsic nature of the whole."¹

Applied to sensory experiences, this principle implies that we do not build up a percept, like a mosaic, by putting together the individual sensory elements, so that the whole-properties are a mere summation of the part-properties; on the contrary, what we perceive primarily are the wholes and their properties, and then first analysis will reveal the parts of wholes. For example, I see a house. From the standpoint of *sensations*, there may be one hundred and twenty distinct sensations of brightness and shades of color in my total impression of the house. But that is not what I actually see; what I see is the 'house' as a 'whole- complex,' and the component parts with their brightness and color properties are but 'parts-of-the-whole- house,' if they are noticed at all. Again, when I behold a city scene, the 'whole view is what I behold first and primarily, and then I notice streets, houses, lawns, trees, automobiles, people, etc., as subsidiary wholes and parts; but I am never aware of a million and more discrete sensations which through addition make up the total scene as a result of their combination.

Such 'wholes' contain more than the mere sum of all the parts, as paradoxical as this may seem. If I take nine distinct tones of different pitch and place them in a definite

sequence, the result, let us say, is a 'melody.' I can arrange them in a different sequence, and the result is a different melody. I can rearrange them again, and now there is no melody at all. In every case, the sensations are the same as to kind and number. 'Melody,' therefore, is more than the mere summation of these nine sensations; it is the 'form' or 'configuration' of the nine tones as a unit or whole which constitutes melody, and that is something over and above the single tones as discrete elements. The 'form' or 'configuration' of the melody becomes still clearer, when we take the melody and transpose it into different keys; we now have totally different sets of nine tones, yet we recognize the 'melody' without difficulty as being the same in every key. We thus see that it is the *form*, the *configuration* of the melody as a whole or unit which determines the nature of the tones as component parts of the melody, and not the nature of the single tones as sensation elements which determine the nature of the melody as a whole. The same is true of the call of a robin, the song of a bob-o-link, the trill of a wren, the hoot of an owl, the moo of a cow, the whinny of a horse, the bray of a mule, the howl of a wolf, the trumpeting of an elephant, etc.; they are perceived as configured wholes and are recognized as such, not as so many separate sensations arising from air vibrations added together to make a numerical total. A symphony by Bach is more than the mere sum of all the separate notes, and a painting by Raphael is more than the juxtaposition of so many particles of paint and daubs of color; the symphony and painting as configured or structuralized wholes are what I perceive,

and the separate parts have importance only in so far as they are integral portions of the whole.

The advocates of the Gestalt theory are certainly correct, when they claim that our percepts are configured wholes and not mere aggregates of elements of sensation. Sensory configuration is a fact, as the above-mentioned instances prove. Perhaps the best proof is found in the case of persons afflicted with cataract from birth and then operated on later in life, because their first acquaintance with visual perception is uninfluenced by past experience.

When conditions were exceptionally favorable, it was invariably found that these patients perceived *objects* and *scenes* as whole-complexes. Trees were seen as trees, houses as houses, streets as streets, persons as persons; but they were not *recognized* as such until they were manipulated or brought into relation with past experiences in some way. These patients could see that a cube was different from a sphere, but they did not know which was the cube and which the sphere until placed in their hand. After a walk through the village, a patient of Dufour remarked that he had seen 'many beautiful things,' but he did not know what they were because he had not been told. We thus see that *configuration* is given immediately in visual perception *interpretation*, however, is an intellectual process. The visual picture of individual objects and scenes is clear and precise, but it has no meaning until connected with the data of other senses, especially with the data of touch and hearing; only after this connection is made, it is possible to interpret the picture and recognize the objects for what they really are.

Experiences of this kind make it clear that things are not perceived as a mere aggregate of disparate visual, auditory, or tactual sensations, but as individual objects, as *configured wholes*; the component parts are present and are also perceived, but as constituents in a secondary manner. *Sensory synthesis* must always be present, because the whole-complex must be seen in relation to its parts, and the parts must be seen in relation to the whole-complex, and because the data of the various senses must be combined into a *perceptual whole*. Only then, after this sensory synthesis is effected, can the intellect proceed to interpret the configured whole and give it meaning. A sensory synthesis, however, demands a special sensory power capable of holding apart and combining the various sensory items. This sensory power is the *central or synthetic sense*. Gestaltists do not admit the existence of a central or synthetic sense, though it follows logically from the facts of their theory. They realize, however, the necessity of a sensory synthesis, and so E. M. V. Hornbostel, for example, argues for the *unity of the senses*.² He does not claim that all the senses are really only one sense, but he stresses the point (unduly, it is true) that the properties of one sense quality are often applied to another sense-quality on the basis of *similarity*. The point is worthy of consideration.

We always speak of tones as 'high' or 'low' in the scale; we also speak of tones as 'warm,' 'cold,' 'sharp,' 'dull,' 'bright,' 'dark,' 'heavy,' 'light,' and so forth. Similarly, we designate colors as 'warm,' 'cold,' 'loud,' 'quiet,' 'soft,' 'hard,' and so on. In this manner we express the fact that

we recognize a definite similarity between the qualities of one sense and those of another, although the sense qualities in themselves are radically different. There is more to this transfer of properties than fanciful language. The basis for this transfer of properties lies in the operation of the *central or synthetic sense*. This internal sense is the common receptacle for the sensations mediated by all the external senses; it holds them apart and yet holds them together, discriminating between them and synthesizing them. The mind notes similarities which at first are not obvious, but which are there fundamentally nevertheless. Language reveals the presence of these similarities in the sensory field of the various senses. Only on the supposition of the existence of a central or synthetic sense does this remarkable feature receive a satisfactory explanation.

The facts brought forth by the psychology of Gestalt in this connection are not really new; they were known in principle by Aristotle and the Schoolmen. They verify the Aristotelian-scholastic concept of the central sense.

Pathology and Central Sense

T. V. Moore³ has shown that *pathological conditions of the brain*, with their attending disturbances, definitely prove the existence of a central or synthetic sense. When such conditions prevail, the afflicted persons lose to some extent the power to synthesize the sensory data into a perceptual whole, even though the single items are all perceived as present.

In the *visual* presentation of an object, we first perceive it as a confused whole and then differentiate the details; we then reform the details into a meaningful whole. For example, we first see an object in a general way as a human person; we then note the details of this person as to color, stature, gait, voice, etc.; we finally reform these details and recognize this person as 'John Jones.' In the case of cerebral disturbances, such as lesions through injury or disease, the power of sensory synthesis is impaired, although the ordinary sensory and intellectual abilities are intact.

Lissauer (1890) describes the case of a man who had injured his head in a fall. He could match colors placed before him, but he made frequent errors when asked to pick out a color by name. He could draw the figure of a watch set before him, but he was incapable of identifying and recognizing either the watch or the drawing; if he took the watch in his hand or listened to it tick, he recognized and named it immediately. When told to draw a figure from memory, he would draw a few strokes, ponder, make a few more strokes somewhere, attempt to group them, etc. The drawing had no meaning for him. Sometimes he recognized a picture as a whole, for instance, an animal, but could not distinguish the head from the tail. He also recognized a bust picture of Bismarck, but was unable to point out correctly the eyes, the ears, etc.

To a normal person the synthesizing of the various items presented in a picture or drawing, if it is not too extensive or complicated in details, is a relatively easy matter; but to a person suffering from a cerebral disturbance of some

sort, it is difficult or even impossible. In order that such a synthesis be effective, it is necessary that the main items be held together in the span of conscious perception long enough for the concrete relations of the parts to become apparent to the observer. The focus of attention passes from one item to the other, but the single items attended to must not fade from consciousness during the successive phases of focusing. Such a fading, however, is precisely what may, and often does, happen in the case of cerebral disturbance; persons afflicted in this manner cannot retain the impressions long enough to make the necessary comparison and synthesis. One patient, for example, was capable of recognizing the single objects and persons in a comparatively simple picture and describe each one separately, but could not hold the items together in consciousness so as to give a correct interpretation of the picture as a whole. Others are able to interpret a single picture, but are unable to interpret a series of pictures in continuity, as in a comic strip. The 'interpretation,' of course, is a function of the intellect. That the intellect failed, however, to make the interpretation, was not the fault of the intellect as such, but the fault of the sensory mechanism furnishing the items for interpretation. That the sensory mechanism is at fault can be observed in those cases where the brain recovers from the injury or disturbance; as the condition gradually clears, synthesis also improves. In some instances patients of this kind return almost to normal. The synthetic function, therefore, is a sensory function dependent on the cerebral centers and their neural associations.

Inability to synthesize *tactual* sensations has also been observed. Dejerine (1906) had a patient who, when a key was placed in his right hand, did not know what it was, although he could give a rather accurate description of it. It was described as "a fairly long object, thin, hard, that has a hole at one end." When it was placed in his left hand, he recognized it immediately and said it was "a key." When the touch spots are insensitive to vibration, because the stimuli, due to some cerebral condition retarding perception, are too slow in reaching consciousness, patients are unable to distinguish between the feel of wool and the feel of glass, etc. Even when capable of recognizing the primary qualities of an object by touch, some persons are unable to recognize the object itself by means of tactile sensations; in other words, the perception of tactile qualities is normal, but they lack the power of synthesizing the perceived data into an integrated perceptual whole.

The lack of perceptual synthesis has also been observed in *taste*. To recognize an object of taste, a combination of the qualities of taste, smell, temperature, touch, and kinesthesia is required; taste alone merely reveals the qualities of sweet, bitter, sour, and salty, without identifying the object itself. One woman patient could readily distinguish the four flavors, but did not know what she was eating.

These and similar pathological cases show clearly that the data of the separate external senses are insufficient to account for the sensory synthesis which occurs in our normal mental life. Over and above the functions of the external senses themselves there must exist the function of

a super-sense intimately connected with the brain. If the function of this super-sense is impaired through cerebral injury or disturbance, normal sensory synthesis is slowed down or partially lost. This super-sense is the central or synthetic sense.

The Nature of the Central Sense

The central sense, it should be clear from what has been stated about its function, is really the *root* and *principle* of the external senses. The external senses are in the nature of instrumental causes in the service of the central sense as the principal cause. The central sense operates through the external senses, collecting divergent data from each of them and synthesizing these data into perceptual wholes, or precepts, so that the organism can know and recognize the single *objects* more or less in their entirety. While the single senses perceive specific sense qualities (proper sensibles), the central sense becomes aware of these qualities and also of the general qualities of bodies based on extension (common sensibles). These common sensibles are movement, rest, figure, magnitude, and number. Our perception of visual space, especially of the third dimension, is mainly the result of the synthetic operation of the central sense using the data supplied by the special senses.

If we now inquire into the *nature* and the *organ* of the central sense, we immediately become involved in difficulties. *Aristotle*⁴ had already realized the problem.

The central sense must be a sensory power, because it is concerned with sense objects; besides, brutes possess this

power, and they are restricted to sense perceptions. Aristotle pointed out that if one person sensed the 'whiteness' of an object (say, sugar) and another person its 'sweetness,' there would be no possibility for them to compare their sensations and combine them in a common percept. The same difficulty, however, seems to arise, if we assume that the central sense is a distinct power residing in a *special organ*. We must bear in mind that this organ would perceive not only the sense *objects* of all the special senses (color, sound, flavor, odor, warmth, cold, pain, etc.) but also the *percipient acts* of sensations (seeing, hearing, tasting, etc.). An organ, however, being material, must consist of parts; every part would perceive the act of sensation and the corresponding object of a particular external sense. We have here practically the case of the two individual persons of whom Aristotle speaks, since each separate part of the organ corresponds to such an individual person; and under such circumstances the comparison, discrimination, and synthesis of the sense objects into a perceptual whole would remain unexplained.

The eye sees color, but it does not see itself see; the ear hears sound, but it does not hear itself hear. No sense perceives its own act of sensation, because that would be a *reflex knowledge* of itself which, as we will see later, is impossible to a material organ. It follows, of course, that a central or synthetic sense is necessary, but the acceptance of a central or synthetic sense does not solve the difficulties.

D. Card. Mercier,⁵ the eminent Belgian philosopher, finds *three serious difficulties* in the assumption that the central sense is a distinct power or faculty with a special

organ. The *first* is that we have two distinct senses perceiving the same proper sense qualities. The eye and the central sense would perceive color, the ear and the central sense would perceive sound, the tongue and the central sense would perceive flavor, and so on. The *second* is, that it would be necessary to ascribe to the central sense such totally disparate things as the perception of color and the perception of seeing the color, the perception of sound and the perception of hearing the sound, the perception of flavor and the perception of tasting the flavor, and so forth. The objects of sense and the acts of sensation are so entirely different in character, that it is difficult to understand how they can stimulate one and the same power and organ into activity. The *third* difficulty is, that the same central sense would become active through the perception of formally diverse objects like color, sound, odor, taste, pressure, warmth, pain. etc. Why all the special external senses, if one sense and one organ can perceive them all?

Mercier is of the opinion that these difficulties can be avoided by assuming that the central sense is *not a special power or faculty with a special organ* determined to the *one specific activity* of discrimination and synthesis. No special organ is required. Synthesis would occur through the functioning of the *cerebral centers* of the single external senses connected with one another by *association fibers*. His explanation then is as follows:

When I grasp a bell and ring it, I have sensations of touch, pressure, temperature, sight, and sound. Each sensation goes to its respective cerebral center. The

simultaneousness of these sensations produces in the cerebrum a *simultaneous reaction* which presents itself psychologically as a *synthesis* of the sensations of touch, pressure, temperature, sight, and sound, and in this manner the object, the bell, is apprehended in its various qualities as a perceptual whole. What more is needed?

Each kind of sensation leaves a cerebral image of its sense quality behind in its respective cerebral center, and all centers are united through association fibers. As a consequence, the visual image of the bell will recall the image of its ringing, its hardness, its temperature, etc.; so, too, the image of the ringing of the bell will recall its shape, etc. If, however, one of these centers should be destroyed or impaired, the cerebral image of this center will also be destroyed or impaired, so that this particular image drops out of the association either entirely or in part. It then happens that persons will not be able to recognize objects by sight or touch or hearing, and so forth, because of a lack of cerebral synthesis. Psychic blindness, psychic deafness, and similar perceptual abnormalities result from such a lack of cerebral synthesis.

In as much as no special structure or cerebral center has been discovered which could be assigned definitely to the central or synthetic sense as the seat of its function, it seems very reasonable to ascribe the central sense and its function to the *brain as a whole*, operating through its centers and association tracks.

Sensory Consciousness

Mercier's explanation of the central sense's function of *consciousness* is also interesting.

We perceive the percipient act of sight, hearing, and of the other special senses. When an external sense is activated to sensation, the muscular apparatus serving this sense contracts and produces muscular or kinesthetic sensations. This muscular sensation, which is the same everywhere, is really what we call sensory consciousness.

As *proof* for his contention, Mercier adduces certain facts. The exercise of an external sense is always *accompanied* by muscular exertion and sensation. In order to see properly, we turn the head and the eyes, fix the focal point and the ocular axis; in order to hear properly, we turn the head in the direction of the sound and strain the ears; in order to taste and smell properly, we move the tongue about and inhale the air through the nose; in order to 'feel' properly, we manipulate an object. In other words, to apprehend an object clearly with our senses, we must accommodate the organ to the object by means of muscular movements. There is thus a permanent *connection and association* between these muscular sensations and the exercise of the sense organs, and the result is the inner perception or 'consciousness' that sensation takes place in a special organ.

Attention to these muscular sensations, as we know, strengthens the consciousness of perceptions. Lack of attention, or the concentration of attention on one type of perception, impedes the consciousness of entire sets of perceptions. Many soldiers, in the heat of battle, fail to

notice minor wounds and experience no pain for a while. Absorption in a problem makes us oblivious of street noises.

According to Mercier's theory, then, consciousness does not manifest to us an internal perception of the act of perception strictly as such. We see or hear or taste or smell or feel something and at the same time have the 'feeling of activity' through muscular sensation. The sentient subject simply perceives *simultaneously a sense object* (color, sound, flavor, etc.) and the *muscular sensation of activity*.

Mercier's theory of sensory consciousness is ingenious, but it does not seem very *satisfactory*. For one thing, the sensations of some external senses are not accompanied by muscular sensations. Such are the sensations of the touch, temperature, and pain spots; they can be aroused by very slight punctiform stimulation, when the muscles are completely relaxed and inactive. The end organs for these sensations are distributed profusely throughout the skin, even in areas where muscle and tendon spindles (the organs of muscular sensation) are not present; one need but mention, for example, the cornea of the eye with its sensitivity to pain. Under such circumstances, we should not be conscious of these sensations; as a matter of fact, however, we are. Again, when the sensory nerves leading from the muscles of a part of the body are severed, muscular sensations from that part of the body are no longer experienced; but other sensations may still be normal and are consciously apprehended as occurring in that part. Finally, the muscular or kinesthetic sense is one of the external senses, on a level with the senses of sight, hearing, touch, temperature, pain, and the others; as such,

this sense is no different from the others. Hence, we are also *conscious of muscular sensations*, as we can easily observe, if we flex our arms or lift a weight. Consciousness, then, cannot be identical with the muscular sensation of activity, but must be something over and above it; otherwise we would be obliged to assume that this second consciousness would thus be the muscular sensation of a muscular sensation.

Mercier's theory, that the synthesizing function of the central sense should be attributed to the brain and its associated centers, is reasonable, and many philosophers hold the same view. His theory of sensory consciousness, however, seems to run counter to observed facts.

Tilman Pesch,⁶ the prominent neo-scholastic, claims that *concomitant consciousness*, or *apperception*, is an essential phase of every act of cognition and therefore also of the function of sensory perception. Every act of cognition (and sensation is such an act) reveals not only the *object which* is presented but also the *subject to whom* the object is presented. Just as it is essential to the act of knowledge (here sensation) that it manifest the thing to the knower, so it is also essential to the act of knowledge to manifest *itself* secondarily and, so to say, 'obliquely' to the knowing (sentient) subject; concomitant consciousness consists precisely in this 'experiential manifestation.' Sensation would not be an act of knowledge, of cognition, if the sentient subject were not aware (conscious) of the knowledge obtained through sensation; and since the knowledge of sensation is negotiated to the subject through the 'act' of sensation, the sentient subject becomes

simultaneously, concretely and concomitantly, aware (conscious) of the act itself. It follows, then, that 'consciousness' is not a specific function of the central sense at all, but is an *essential property of all cognitive functions* of whatever kind.

Obviously, of course, some ultimate principle of unity is demanded to link the cerebral centers and their separate functions and data together. This principle must be the *unitary nature* of the percipient subject, based upon a single *vital principle* of sentiency which is predominantly active in the centralizing organ of the brain.

Summary of Chapter VII

The internal senses are: The central or synthetic sense, imagination, sensory memory, and instinct. This chapter deals with the central sense.

1. *The Central Sense.* It is also called the 'common sense and the 'synthetic sense,' and is defined as the mental *power to consciously perceive, distinguish, and synthesize the objects and operations of the presently active external senses.* A double function is ascribed to it: It perceives and distinguishes the sense qualities presented, combines them, and refers them to one object; it also makes us aware of the percipient acts of sensation. In this latter capacity it is termed 'sensory consciousness.

2. *Existence of the Central Sense.* Introspection shows that we distinguish between the 'whiteness' and 'sweetness' and 'hardness' of sugar, etc.; also, that we *combine* them and refer them to the same object. Since the single senses respond only to their respective stimuli (the eye to light, the ear to sound, etc.) and not to those of other senses, they cannot make the synthesis; a central or synthetic sense is required. Brutes also possess a central sense, as their actions show.

Introspection also reveals that we are conscious of the percipient acts of sensation; we not only see, hear, etc., but are aware that we see, hear, etc. Brutes, too, have this consciousness.

The fact that we have different *kinds* of senses, makes a central, synthetic sense necessary, otherwise our mental life

would consist of a mass of isolated, unrelated sensations.

3. *Gestalt and Synthetic Sense*. For the isolated discrete psychic elements of sensationalism and associationism, Gestaltists substitute 'organized wholes,' 'configurations,' 'Gestalt.' The whole is prior to the parts; the parts derive their character from the whole, not the whole from the parts. What we perceive primarily are the wholes and their properties, and then first will analysis reveal the parts of the wholes. Much experimental evidence is adduced to prove the truth of this fundamental fact of mental life.

Sensory synthesis must always be present in the perception of configured wholes. Such a sensory synthesis, however, demands a special sensory power capable of holding apart and combining the various sensory items. This sensory power is the *central or synthetic sense*.

4. *Pathology and the Central Sense*. Due to cerebral disturbances and lesions, the power of sensory synthesis is impaired or partially lost, although the ordinary sensory and intellectual abilities are intact. Hence, the data of the separate external senses are insufficient to account for sensory synthesis. The central sense in such cases is impaired.

5. *Nature of the Central Sense*. If one assumes that the central sense is a distinct power residing in a special organ, grave difficulties are encountered, because one part of the organ would presumably perceive one thing, and another part another thing; and thus a synthesis seems impossible.

Mercier is of the opinion that the simultaneousness of the sensations produces in the cerebrum a simultaneous reaction which presents itself psychologically as a synthesis;

hence, the central or synthetic sense and its functions should be ascribed to the brain as a whole. This is a reasonable theory.

6. *Sensory Consciousness*. Sense consciousness, Mercier contends, is nothing more than the muscular sensation which accompanies seeing, hearing, etc. Tilmann Pesch insists that consciousness is an essential phase of every act of cognition, including sensation, otherwise sensation would not be 'cognition'; hence, consciousness is not a specific function of the central sense at all.

The functions of the central sense ultimately demand a *vital principle* as the principle of unity.

Chapter 8

IMAGINATION

WE HAVE NOW ADVANCED ONE STEP FARTHER IN FOLLOWING THE progressive stages of human knowledge. Objects stimulate the various sense organs into activity. These organs transmit nerve impulses to the brain, and the organism responds with the sensations appropriate to the stimuli. Sensations reveal a number of qualities, such as color, sound, flavor, warmth, cold, and so on. Then the internal central or synthetic sense combines these different sense qualities into a perceptual whole by referring them to the same object. This meaningful impression of the object obtained by the use of the senses is called the *percept*. The percept, therefore, is the sensory representation of the object as it appears to the activated senses and the central sense.

It is the purpose of this entire process to make us acquainted with the *objects* existing in the world in which we live. This purpose, however, would be only incompletely realized, if the impression of these objects would disappear when the objects themselves disappear, because then we could have no abiding *knowledge* of them. One of two things is necessary, if we are to have an abiding knowledge

of objects: either the objects must remain present to our senses all the time, or we must have internal images of the objects present in us all the time. The first alternative is practically impossible and, as a matter of fact, does not occur. The second alternative, therefore, is a natural necessity, and nature has provided for this requirement of knowledge in the internal sense of *imagination*.

The Concept of Imagination

The *imagination* can be defined as the *power to form mental images or phantasms of perceived objects, together with the ability to reproduce these images or phantasms even in the absence of the perceived objects*.

The term 'image' or 'phantasm' must be taken broadly so as to include the representations of all the senses. We can imagine the color and shape of a rose (visual image), the fragrance of an orange (olfactory image), the taste of sugar (gustatory image), the tickle of a feather (touch image), the weight of steel (pressure image), the song of a canary (auditory image), the temperature of the yearly seasons (warmth and cold image), the misery of an operation (pain image), the strain of running (kinesthetic image), the sensation of falling (static image), the ache of hunger (visceral image).

The *differences between percepts and phantasms* or images are noteworthy. Upon comparison, we find that percepts are vivid and strong; phantasms are pale and weak. One need but look at a street scene, in order to observe the vividness and strength of the visual picture; the

same view, as reproduced by the imagination with closed eyes, is extremely pale and weak. Percepts are unchangeable for the will; phantasms are changeable. So long as the stimuli reach the senses, they produce their effects, and our will can do nothing to alter them; the imagination, however, is dependent on the direction of the will, so that the will can decide what phantasms shall remain present or be eliminated. When we listen to a song on the radio, we hear the melody just as it is rendered by the singer; but when we imagine a song, we can change the melody at any point and even stop it entirely. Percepts possess clarity and fullness of detail; phantasms are vague and indistinct. Look at a bouquet of flowers and note the clarity and fullness of detail in shapes and colors; then close your eyes and imagine the same bouquet, and the details give way to vague and indistinct impressions.

These characteristics of percepts and phantasms are indicative of the *difference between the central sense and the imagination*. The central sense receives its data from the external senses and is directly dependent on the stimulation of these senses in its own proper function; hence, it never operates except when the external senses function, and it occupies itself exclusively with the objects presented by these senses. The imagination receives its data from the central or synthetic sense and then forms phantasms of the objects, and these phantasms can be revived even when the originals, the objects, are absent; the imagination, therefore, does not occupy itself with the objects, but with images in so far as they are representations of these objects. The causes which produce

the percepts exist outside of us, as a rule, and are beyond our control; but the causes which produce the phantasms exist entirely within us and are, to a great extent, subject to our control. Because of these conditions, the percepts come into existence as items in a series fixed according to time and place, following the spatio-temporal order of the physical stimuli; but the representations of the imagination, being derived from the stored-up images always present after their formation, are capable of being evoked, separated, or combined in various ways and can be arranged in a series totally different from that in which the original perceptions occurred. The products of the central or synthetic sense are *presentations* of immediately present objects; the products of the imagination are *representations* of these objects in the form of phantasms.

Imaginal activity thus reveals three distinct features of the imagination: *formation and conservation* of the images of sense objects; *reproduction* of the images; *construction* of the images into new combinations. We therefore speak of the 'conservatory' imagination, the 'reproductive' imagination, and the 'constructive' imagination. In speaking in this manner, we do not mean to imply that there are three distinct imaginations in man; there is but one imagination with three phases to its normal activity.

The Conservatory Imagination

Somehow or other, we *conserve* the 'images' or 'phantasms' of previous sensations and perceptions in our imagination; or, at any rate, we conserve something which the

imagination elaborates into 'images.' Our daily experience proves that we are able to revive these images, not only once but hundreds of times. The ability to revive them presupposes the conservation of these images or of something which gives rise to them.

Certain *ultra-spiritualist* philosophers, such as Herbart, Sir William Hamilton, and others, look upon the conservation of images as taking place in the *mind or soul alone*, independent of neurological processes and of the brain; brain and nerve substance have nothing to do with the conservation of images. If this theory were true, a number of facts are unintelligible. Drowsiness retards the revival of images; tea, coffee, and some drugs increase the flow of images, while other drugs decrease their flow; in old age the conservation of images is weaker than in youth; diseases and injuries of the brain blot out entire sections of kindred images producing psychic blindness, psychic deafness, etc., leaving others intact and revivable; tumors of the brain often disturb imaginal functioning, and the functioning sometimes returns to normal after removal of the tumor; fatigue interferes with the retention of impressions. Facts of this nature show definitely that the conservation of images is not a purely psychic process, but is dependent at least to some extent on physiological conditions and neurological processes, especially those of the brain.

Materialistic psychologists and philosophers, among whom are Bain, Spencer, Ribot, and many others, place the conservation of images on a purely *neurological* basis. Cerebral processes alone are involved in conservation.

These psychologists and philosophers differ in the details of the theory, but the general view is that the sensory impulses produce a modification in the tissue of the fibers and cells of the brain. Ribot, for example, assumes a definite modification of neural elements. The molecules of a nerve cell are forced by the nerve impulse to oscillate in a particular manner and do not return to their original condition; a repetition of this process tends to fix the molecules in this state of modified action; a number of such neural elements become connected through dynamic association, and thus entire events are recorded. Others look for the trace of the images in the grooving of pathways through groups of neurons and fibers brought on by repeated stimulation; the neural mechanism would be something like a new engine which must be 'broken in' and then runs smoothly, because it is grooved in a definite direction.

That some sort of modification of the nerve substance actually occurs and plays a part in the conservation of images, is undoubtedly correct. But that such neurological processes should be accepted as the complete explanation of the conservation of images, is an inadequate theory, because it is too mechanistic and ignores the psychical features of the images.

To say that sense perception leaves in the cerebrum a weak *representation*, a *faded copy*, or a vestige, is merely a restatement of the problem. What sort of a weak representation or faded copy of a color, a sound, a flavor, or of a pain can exist in the brain? If present, would we not be conscious of them? Our experience is to the effect that we

can revive such images, sometimes voluntarily and sometimes involuntary, but they are not present *as images* until revived.

We can, and probably must, admit that some sort of image trace or, as Wundt terms it, '*functional disposition* of the nervous substance' remains in the neural elements after sense perception. More, however, is required. 'Traces,' 'dispositions,' 'oscillations,' or 'grooved pathways' of nerve tissue and cells are *not images*. What similarity is there between these things and the imaginal phantasms representing the Battle of Pearl Harbor, an Army and Navy football game, a morning in the Alps, the Bay of Naples, the bustle and hubbub of the port of Hong Kong, the death scene of a dear relative, the rhapsody of a symphonic orchestra, or the misery of a painful illness? Most of the events and scenes relived with the greatest vividness in our imagination have occurred *only once*, and thus a repeated stimulation of the same cells never took place to produce a modification of molecular grouping or grooved pathways of functional dispositions. Furthermore, when we look at a scene, the visual image covers the entire retina; looking at other scenes immediately after, we cover the same retinal elements with new visual images; and this process occurs hundreds of times in succession. One set of brain cells certainly does not select the impulses of one retinal image and conserve its trace exclusively, and another set the trace of another image, and so forth with the retinal images of all the successive visual impressions. The *same cerebral cells* receive the nerve impulses of a multitude of visual images; and since there is no reason to assume a preferential

selection of traces on the part of the cerebral cells, these traces should overlap and interfere with each other, something like multiple exposures on the same photographic plate. No such confusion of images, however, takes place, because each scene or event can be reproduced as a *whole*. Again, if an identical tone is sounded, say, four times in succession, the impulses should reach the same cerebral spot along the same fibers, leaving a single reinforced trace or groove, and one should be able to revive only a single image of this tone; as a matter of fact, however, our imagination revives the whole event as a tone sounded four times.

The simple fact is that neural modifications of the cerebrum can no more be the full and exclusive explanation of the conservation of phantasms than the activations of sensory nerve terminals by physical stimuli are the full and exclusive explanation of the original perceptions of which the phantasms are the imaginal representations. Just as there is more to a perception than the molecular vibration of a nerve cell, so there is more to a phantasm than the molecular modification of a brain cell. Perceptions and imaginal phantasms involve the mental element of conscious cognition, and *conscious cognition* is something *psychic*, not purely physical; there is a *meaning* in what we perceive and imagine, but there is no meaning in the molecular oscillations of brain cells or in the grooved pathways of cerebral substance concerning whose existence we are totally unconscious.

The ultra-spiritualistic and materialistic theories are oversimplified extremes. Perceptions and phantasms are

neither purely psychical nor purely physiological, but *psycho-physiological*. Cortical centers and cortical cells are necessary conditions for the conservation of phantasms, as is evident from the fact that injury to certain cortical centers makes the storage and revival of imaginal phantasms at times impossible. On the other hand, phantasms have a cognitional element which is truly psychical in character, and as such they demand a mind or psyche capable of cognition as distinct from mere neurological function. The psychical and physiological features of the phantasm and its 'trace' are interdependent, because man is a *psycho-physiological* organism. The phantasmal 'trace,' or whatever it is that is stored and conserved, must, therefore, also be psycho-physiological.

'What, then, precisely is this 'trace' or 'vestige' or 'disposition' which underlies the phantasm or image of the conservatory imagination? Frankly speaking, we do not know. Something of the sort must be assumed to exist and be conserved; otherwise we cannot explain how the phantasms can arise after the actual perceptions have disappeared, sometimes even after the lapse of decades. It is likely that the phantasmal trace is such that a direct examination of its nature either by introspection or by experimental methods is not possible. And so the workings of the conservatory imagination may never actually become known.

The Reproductive Imagination

The *reproductive imagination* is the imagination in so far as it has the power of forming phantasms of objects and events which have been previously perceived. It should be noted very carefully that what are reproduced here in phantasmal forms are objects and events as *they have been perceived* at one time or other in actual experience, though at present they are no longer before the senses. It is not necessary that they be recognized as having been previously experienced; 'recognition' is a function of memory.

Just as we do not know exactly how the phantasmal trace is stored by the conservatory imagination, so we do not know how the reproductive imagination elaborates the phantasms from these traces. Someone says 'Times Square in New York,' and there rises up within our imagination the visual phantasm of this famous triangular thoroughfare with its crowds, theaters, stores, and bright lights. Someone mentions 'Lohengrin,' and the auditory phantasm of the wedding march begins to unfold in stately rhythm. Someone speaks of 'army grub,' and the gustatory and olfactory phantasm of corned beef and canned salmon assail the consciousness of the former soldier. And so with other experiences of the past. How are these phantasms evoked and evolved? The inner mechanism is hidden in the recesses of the mind.

Through experience we know that our imaginal phantasms are not isolated fragments of mental phenomena; they are *associated* with one another. The reproduction of related phantasms is called *association*, and the principles which condition the reproduction of a related set of phantasms are called the *Laws of Association*. That

reason and will exert a powerful influence on the reproduction of phantasms and associate them freely, can be observed in the composition of a song, a poem, a book, etc. In the present connection, however, we are concerned only with *involuntary* association.

Laws of Association

There are primary and secondary Laws of Association. The primary are: the law of contiguity, of similarity, of contrast. The secondary are: vividness of impression, frequency of repetition, recentness.

THE PRIMARY LAWS OF ASSOCIATION

The Law of Contiguity. By this we mean the tendency of the imagination, in the presence of objects or events or in the presence of the phantasms of such objects or events, to recall other objects or events *connected* with them *in time or in space*. 'Contiguity' is really a spatial concept, but here it is used in the sense of 'closeness' in time as well as in space. This law is the formulation of a fact of common experience.

If I see or imagine my childhood home, there immediately arise before me objects and events connected with that place and period of my life: neighboring houses, streets, companions, relatives, events of school life, games, adventures, etc. If I imagine World War II, this recalls the attack on Pearl Harbor on December 7, 1941, the Japanese campaign against the Philippines, Malaya, Java, Burma,

etc., or it may recall the succession of events and places connected with the Axis campaign in Europe and North Africa, etc. The techniques of art and skill all involve associations in time and space; whenever I practice or merely imagine a certain technique, a succession of temporal and spatial phantasms referring to its performance passes through my imagination. All *learning* depends on associations of objects or events contiguous in time or in space. As a rule, such associations contain elements in both time and space.

The Law of Similarity. This law states that present phantasms of objects, events, perceptions, and so forth, tend to reproduce in our imagination similar experiences of the past. We read, for example, an account of the French Revolution and are immediately reminded of the American Revolution. We see a scene on the Rhine and our imagination pictures a similar scene on the Hudson. We look at the photograph of our mother, and we recall her person. The law also applies to perceptions of taste, smell, pain, touch, temperature, etc. The *esthetic pleasure* derived from the arts of painting, poetry, sculpture, drama, opera, and so forth, is based to a great extent on imitation and the suggestion of similarly experienced or imagined things and events.

The Law of Contrast. This law states that present phantasms of objects, events, perceptions, and so forth, tend to reproduce in our imagination *contrasted* experiences of the past. It is a well-known fact that if one member of a pair of contraries is mentioned or imagined, the other member of the pair readily suggests itself: hot-

cold, black-white, rich-poor, health-sickness, young-old, up-down, north-south, quiet- loud, pleasure-pain, full-empty, and so on. Viewed superficially, this linking of contraries is one of the oddest facts of our mental life, because there seems to be no associative bond between such opposites. Upon closer inspection, however, it will be seen that the Law of Contrast is really a combination of the Laws of Similarity and Contiguity. These opposites are the extremes, the beginning and the end, of a common series; and the beginning and the end of a series are similar in this that they are terminal points. For this reason, too, it is customary to mention the extremes of a series in the same sentence, because thereby, in a way, we cover the entire series; we thus have the association of contiguity in thought and language.

Obviously, the lines of associations as expressed in these laws frequently converge and combine, so as to strengthen the bond between imaginal phantasms. We then speak of *compound, complex, or cooperative associations*. To many a soldier the word 'New Guinea' will recall the countryside, the din of battle, the death of a comrade, wounds, destruction, pride in victory, patriotism, and many other things. Reversely, there are *conflicting or obstructive* associations which impede the recall of a desired image by diverting the mind through counter-associations. We may wish, for example, to recall a certain melody; but a somewhat similar melody forces itself upon our imagination, and we are unable to rid ourselves of it, thus blocking the path for the recall of the melody desired.

The Secondary Laws of Association

Vividness of Impression. When an impression is very vivid, either in its very nature or because of its accompanying circumstances, such an impression is more readily reproduced by the imagination. No picture or description can impress us so deeply as the actual participation in a stirring event. No king will forget his coronation, no president his election, no mother the birth of her child, no author his first book, no soldier his baptism of fire.

Frequency. The more frequently an impression is repeated, the easier it is to recall. Hearing a person's name once, listening to a melody once, reading a poem once, viewing a scene once, etc., does not create a strong associative bond as a general rule. Frequent repetition, however, has a tendency to reinforce an impression, and through this repetition its reproduction is facilitated. Frequency is usually the basis of learning.

Recentness. When an impression has occurred recently, its trace is still fresh, and the reproduction of the impression by the imagination encounters little difficulty. When, however, many other impressions intervene between occurrence and recall, the traces of the older impressions are weakened and perhaps even obliterated. It may be comparatively easy, for example, to reproduce through our imagination the main events of the last week, but well-nigh impossible to recall those during the same week a year ago.

It is unquestionable that association plays a very prominent and important part in our mental life. A knowledge of the laws which govern association should

enable us to apply these laws intelligently for the practical purposes of everyday existence, particularly in mastering the techniques of our profession or occupation. A genius may be born, but even a genius must develop his native abilities.

The Constructive Imagination

The *constructive imagination* is the imagination in so far as it has the power to unite phantasms which, in *this* particular combination, have never been experienced by the subject. We observe its free workings in dreams and fancies, its controlled workings in the products of art and science. In all these activities combinations of phantasms occur which, prior to the imaginative function, represent things never perceived by the individual in question. The result of the function of the constructive imagination may be the phantasm of a single object, such as a winged horse or a castle in the clouds, or it may be the phantasms of a series of events, like the Iliad of Homer or a trip to Mars.

Except perhaps in dreams and free fancies, the workings of the productive imagination are strongly influenced, and often almost completely controlled, by the *intellect and will*. The arts and sciences are proof of the influence of intellect and will in the products of the imagination.

The Arts. We speak of the 'creations' of art. Strictly speaking, the artistic imagination does not create; it merely unites images taken from the various sensory impressions with ideas of the intellect and combines them into beautiful forms which are an idealization of the real and a realization

of the ideal. The total effect is an esthetic whole which is a work of art, a supreme achievement of the constructive imagination. The *Hamlet* of Shakespeare, the *Divina Commedia* of Dante, the *Pieta* of Michelangelo, the *Sistine Madonna* of Raphael, the *Parsifal* of Wagner, the Cathedral of Rheims — these show the productive imagination of human genius at its best, because they are an expression of culture in its highest form. Needless to say, imaginative art may assume humbler forms, as we observe it in a mother's lullaby, a child's play-acting, a boy's fancy diving, a girl's crocheting, a man's sales talk, and so forth. Even the appliances of the household are embellished by the artistic touch of man, so that a utilitarian article becomes a thing of beauty.

Science and Invention. Many discoveries and inventions of a scientific character were the result of fortunate accidents. As a rule, though, they were the outcome of laborious research. Research means the formulation of hypotheses, and hypotheses are the imaginative construction of probable assumptions concerning causes and effects. Research means the imaginative application of general principles to problematical particular instances and the imaginative synthesis of isolated facts into problematical universal laws. Research means the imaginative devising of instruments, ranging from Geiger counters for trapping individual electrons to giant telescopes for studying immeasurable galaxies of stars. Research means the imaginative development of experiments for the verification or disproof of scientific theories which may affect the welfare of entire nations and

change the course of history. Modern civilization, in a great measure, has been profoundly influenced by epoch-making inventions, such as the telephone, the locomotive, the steamship, the automobile, the airplane, the radio, and such inventions are the products of man's imagination applying the principles of science to the needs of life. There has not been a single instrument, from a wheel and a knife to a turbine generator and a rotary press, which does not show the impress of the constructive imagination of an inventive genius. Nor has there been a single science, starting from a few disconnected facts and ending in a grandiose synthesis of all relevant facts and laws, which could have developed into a system of knowledge without the aid of the imagination of a host of scientific workers.

It is true, of course, that the constructive imagination, operating with sensory phantasms only, could never achieve these results; it must be controlled and directed by the intellect and will. But it is equally true, that the intellect and will derive their data concerning the outside world from the perceptions of the external senses and the phantasms of the imagination; without this assistance, as we are at present constituted, intellect and will would be helpless powers of the organism as a whole. It would be more accurate to speak of the 'constructive imagination' as being the imagination and the intellect in collaboration.

THE *DEVELOPMENT* OF THE CONSTRUCTIVE IMAGINATION IS interesting, for it follows closely the biological development of man himself.

In *children* we observe the first stage of development. One of the outstanding activities of the constructive imagination of the child is its tendency to interpret inanimate things as living. To the little girl the doll is always a real baby, and to the little boy the teddy bear is always a real animal. Not that they actually believe it; their imaginative fancy is at work. The child also shows its constructive imagination in its play. Girls can spend an entire afternoon playing house, and a boy will build house after house with blocks. Another feature of childhood imagination is the love of fairy tales and narratives. Children will listen with rapt attention to the stories of Little Red Riding Hood and of Jack and the Beanstalk. In our day father and mother must read to them the adventures of the comic strip.

In *youth* the constructive imagination finds its outlet in games and competitive sports. In the early part of youth the games are still very imaginative, but a considerable amount of bodily activity is required. This period helps to develop muscular coordination and mental ingenuity. In the latter part of youth, the games become more and more strenuous, and the competitive spirit is strongly emphasized. Sport, for sport's sake, predominates. Games and sports serve the purpose of preparing the girl and boy for the serious duties which lie before them in after-years. At the end of youth, the element of sex enters strongly into the workings of the imagination. Sex interest is revealed in the type of books the young folks read and in the social events which they enjoy.

In *adulthood* a further radical change occurs. The constructive imagination is now employed in the serious problems of life, the foundation of future social security, the rearing of a family, the complete development of all bodily and mental faculties. What was begun in childhood as a matter of sheer fancy has grown into mighty forces for good or evil in the battle of individuals and of nations. The boy and girl have become the man and woman, upon whose shoulders rests the burden of civilization.

Some Phenomena

In our normal waking state the activities of the imagination are checked by the constant impact of stimuli impinging on the external senses and by the control of intellect and will. A completely uncontrolled imagination in our waking states is a comparatively rare occurrence. It is in *dreams* that the imagination has free play.

Dreams possess a number of characteristic features. In sleep the activity of the cortical centers is in abeyance, so that outside impressions lose a great amount of their correcting influence. As a result, dreams have a decided *appearance of reality*. There is also a *lack of coherence*. Since intellectual criticism and voluntary control are missing, the scenes and events pictured in dreams shift about in kaleidoscopic fashion, frequently ending in something entirely different from the beginning, because the imagination seizes upon an accompanying association and promptly veers off in that direction. Nevertheless, there is, as a rule, a certain *degree of consistency* in

dreams, probably due to sets or configurations of associative bonds present in the imaginal material. Since striking images stand out among the vague mass of fleeting phantasms, they acquire disproportionate value for the moment, and that probably accounts for the *exaggeration* so noticeable in dreams.

As for the *stimulus* of dream states, it is safe to assume that some dreams originate from auditory, pressure, temperature, and visceral sensations dimly experienced during sleep. Other dreams undoubtedly have their start in worries, problems, fears, unsatisfied desires, etc. Many dreams have the definite character of *wish-fulfillment*. Freud made wish-fulfillment the basis of his technique of *psychoanalysis*, but he gave it a one-sided development by insisting that the wish-fulfillment of dreams is based almost exclusively on inhibited sex desires. It is true, of course, that sex desires may and do play a prominent part in dreams, due to the repression of sex impulses in normal waking states; during sleep such impulses are practically out of control and rise to the surface, thereby producing dreams of wish-fulfillment with a sexual content. It is unwarrantable, however, and a distortion of fact, to interpret all dreams in terms of ultimate libido, as Freud and the regular psychoanalysts do. *Fear*, with its corresponding emotions, is also a dominant factor provocative of dreams, and such dreams should be interpreted as simple expressions of fear, without having recourse to a very obscure and doubtful symbolism of hidden sexuality. Thus, the horror dreams of soldiers, who have gone through the ordeal of a terrifying battle, should

be laid to the fear for personal safety and not to suppressed libidinous desires. Similarly, many dreams are the play of *indifferent* images which happen to cluster around some impressive event which occurred in a recent experience; to interpret them in any other way is to do violence to simple facts. There is no absolutely uniform pattern of dreams originating from a single type of stimulus.

An interesting phenomenon of imagination activity is *eidetic* imagery. An eidetic or eidetiker is an individual who can form images of unusual clarity and vividness, so that these images are faithful reproductions of the original sensory experiences. The power of forming eidetic images is found in some children and is lost at about the age of puberty; in very exceptional cases it persists into adulthood. If a picture is placed against a gray background, and the child scans it for 10 to 15 seconds, then, upon removal of the picture, the child apparently still sees the original picture as if projected against the neutral background; this image of the original picture is the eidetic image. The child will not only describe, but point out, the details of the picture as if the picture were still there. If the gray background is turned around, the eidetic image travels with it (apparently), and the child sees it upside down. The accurate description of the details shows that it is not a question of memorizing the contents of the picture, because the time of exposure is too brief for memorizing so many details; the eidetiker simply 'sees' the picture. Experiments have been made with 'double' pictures which represent one face when placed erect, and another face when placed upside down. The eidetiker, of course, is left in ignorance of

this peculiarity of the picture; when the background is turned upside down, the eidetiker is surprised to see a new face before him. It would be erroneous, however, to think that eidetikers 'see' the entire picture just as presented originally; the picture seems to take on detail as they visualize it by going from one part to another. Eidetic images are usually of the visual type, but experiments with other types have also been successful. Most eidetikers are able to recall their eidetic images after the lapse of some time. It is probable that the individuals termed 'lightning calculators' are really eidetikers, because eidetic children have been known to still 'see' the figures of a problem on the blackboard even after the figures were erased. In as much as the power to form eidetic images is nearly always lost at about the advent of puberty, it seems to be based on biological factors; just what these factors might be, is still unknown. Even a change in diet, in some cases, alters the eidetic imagery. E. R. Jaensch and his collaborators have done good work in this field.

It is a well-known phenomenon of imaginal phantasms that they have a certain *motor character* and *motor effect*. Actual perceptions are usually accompanied by muscular contractions of some sort. The phantasms, since they are representations of perceptions, naturally include such motor images, and as a result incipient movements of the musculature accompany phantasms. There is always the tendency present to carry out the motor part of the phantasm through appropriate muscular action. When we make an intensive task of memorizing an address, we unconsciously form soundless words with our tongue and

mouth. Imagining that we are playing a musical instrument produces in us a faint impulse of performing the action itself. The vivid imagination of a fine meal stimulates the salivary gland and induces salivation. The passenger in an automobile, sitting alongside the driver as he wends his way through congested traffic, feels the impulse to step on the brake and finds that he has pressed his foot firmly against the floor boards. Watch the crowd at a tense moment in a sports event, such as a football game, tennis match, horse race, bowling, baseball, basketball, etc., and note that practically all execute some movements reflecting the action of the players.

This motor character of phantasms explains a number of curious phenomena in human behavior. There is the fact of unconscious *imitation*. Someone yawns, and soon everyone present is yawning. Someone has a hearty, infectuous laugh, and, before we realize it, we are smiling or even laughing, without knowing what it is all about. The passion-charged actions of the actors in the 'big moment' of a drama electrify the audience on the other side of the footlights, and the audience lives the scene with the players to such a degree that it laughs, weeps, and becomes almost hysterical. Mob psychology is based on this fact. *Sleepwalking* is another instance of the power of the motor character of phantasms. In the waking state we check the motor impulse of phantasms and stop the resultant actions before they become pronounced. In sleep some persons are incapable of checking the impulse, and it then happens that motor dreams are carried out through a train of completed bodily actions. The actions performed in *hypnotism*

undoubtedly admit of a similar explanation. The hypnotized persons in a deep trance resemble sleepwalkers in so far as they are unconscious of their surroundings and cannot check the motor impulse produced by the phantasm; they differ from sleepwalkers in this, that their imagination is open to the suggestions of the operator, to whom alone they pay attention. When given a suggestion involving certain actions, the suggestion awakens the motor phantasm in their imagination, and the command of the operator is automatically carried out.

Other important, though abnormal, phenomena pertaining to the activity of the imagination are hallucinations and delusions. Some persons have subjective perceptual experiences which lack obvious sensory stimuli; although the senses receive *no relevant stimulation*, such persons erroneously perceive facts as present to the senses which are not actually there. These erroneous perceptual experiences are termed *hallucinations*. Sensations, as a rule, play their part in hallucinations, but the imaginal content plays the dominant part in the total experience; in some instances, actual sensations are a negligible factor or may be, so far as can be discovered, entirely missing. Some hallucinations involve a single sense only, others involve a combination of senses; one subject, for example, may have merely a visual or auditory or tactual hallucination, while another may experience a complex hallucination combining visual, auditory, and tactual imagery. The causes may be organic (toxic conditions, injuries, etc.) or psychic (fears, anxieties, etc.). In *delusion*, on the other hand, the subject suffers from a mental disorder which manifests itself in a

misinterpretation of the general state of affairs; delusion is due to an error of judgment rather than to an error regarding the facts immediately present to the senses. A delusion is characterized by a false belief of judgment regarding the self; such is the delusion of grandeur or of persecution, found in some forms of insanity or mental disease.

The activities in the imagination show plainly that, over and above the functions of the neural mechanism itself, some *unifying principle* is demanded, in order to account for the conservation, reproduction, and construction of phantasms. Since these phantasms combine the general qualities of the various sense objects into unified wholes, the separate cerebral centers, individually and collectively, are incapable of effecting the unification. Here again, man is seen to be an *integral organism*, in which the biological functions and the psychic functions are coordinated into a vital unit.

Summary of Chapter VIII

In order that we may have an abiding knowledge of objects in their absence, we must retain the contents of perceptions in the form of images. The imagination performs this function.

1. *The Concept of imagination. It is the power to form mental images or phantasms of perceived objects, together with the ability to reproduce these images or phantasms even in the absence of the perceived objects.* Its functions are: the formation and conservation of images; their reproduction; the construction of images into new combinations.

2. *The Conservatory imagination.* Ultra-spiritualist philosophers place the conservation of phantasms in the soul or mind alone; materialistic philosophers place it on a purely neurological basis. The former are wrong, because bodily factors facilitate and impede conservation; the latter are wrong, because psychical factors are involved, in as much as phantasms contain the mental element of conscious cognition. Imaginal phantasms have a *psycho-physiological* character. We do not know the exact nature of the 'trace' which underlies the phantasm, nor do we know how it is conserved.

3. *The Reproductive imagination.* It is the power of forming phantasms of objects and events which have been previously perceived. The reproductions of related phantasms is called 'association.'

4. *Laws of Association.* The primary Laws of Association are: contiguity in time and space; similarity; contrast. The secondary Laws are: vividness of impression; frequency; recentness.

5. *The Constructive imagination.* It is the power to unite phantasms which, in this particular combination, have never been experienced by the subject. Constructive imagination plays a prominent part in the arts and sciences. It passes through various stages of development in childhood, youth, and adulthood.

6. *Some Phenomena.* Dreams are the products of free imagination. Psychoanalysis makes use of dreams. *Eidetic* images are images of unusual vividness and clarity, so that they are faithful reproductions of the original sensory experiences. These images seem as if projected externally. Phantasms have a certain *motor character*; incipient movements of the musculature accompany phantasms. The motor character of phantasms results at times in imitation, sleepwalking, and in hypnotic actions. *Hallucinations* and *delusions* are abnormal phenomena in connection with the imagination.

Like the central sense, the imagination ultimately demands a vital principle as the principle of unification.

Chapter 9

MEMORY

IN REVIEWING THE PROGRESSIVE STAGES OF OUR SENSORY knowledge discussed so far, we find that this knowledge proceeds along the following lines. The exteroceptive, interoceptive, and proprioceptive senses respond to stimuli from objects and send nerve impulses to the brain; the response is a definite sensation of color, sound, flavor, pain, etc. The central or synthetic sense then consciously compares, distinguishes, and combines these various sense qualities and refers them to their respective objects, thereby forming perceptual wholes. The imagination thereupon accepts the data of the central sense and fashions a phantasm or image of the perceived object; this phantasm leaves a trace or disposition in the imagination, so that the phantasm is revivable, either voluntarily or involuntarily, in the absence of the object and its stimuli.

The objects of sense do not remain in our presence. If the knowledge of these objects is to be true knowledge, we must be able to refer the information contained in the phantasms to the definite objects for which they stand. We must, therefore, be able to *recognize* (recognize, i.e., cognize or know again) the objects and the experiences

represented (represent, i.e., make present again) by the imaginal phantasm. Recognition is the function of *memory*.

The Concept of Memory

By *sensory memory* we understand the *power to recall past objects and states of consciousness and recognize them as having been present in former experiences*. The characteristic feature of memory is the concrete recognition of something as having been present before.

Many psychologists and philosophers refer the entire process of the retention and reproduction of past images or phantasms to memory. The expressions 'memory trace' and 'memory image' are common phrases. Many also bring the Laws of Association into connection with memory. This is permissible, but it must be borne in mind that the retention and reproduction of the images of objects and events does not necessarily involve memory. Oftentimes objects and events, which were actually a part of past experiences, are reproduced by us in phantasmal form at a later date, but we do not recognize and remember them as having been previously experienced; when confronted by such objects or events, or when someone calls our attention to them, we confess that we "do not remember them." We thus have retention and reproduction, but not memory. Hence, retention and reproduction are more properly functions of imagination than of memory. The *distinctive element* of memory is the *recognition of past objects and events*, not their phantasmal retention and reproduction.

Maher gives the following concise description of the *difference* between imagination and memory. "The chief features in which remembrance differs from mere revival of images are: (1) The freedom of the imagination as to the number and variety of its acts, the limited character of our recollections; (2) the casual and variable order of the former states, the serial fixity and regularity of the latter; (3) the isolated nature of imaginary events, the solidarity or relatedness of remembered occurrences, which are inextricably interwoven with multitudes of other representations; (4) finally, the peculiar reference to my own actual experience involved in the act of identification or recognition, which forms part of the recollection but is absent from the creations of fancy."¹

The reproductive imagination and memory are closely connected. The imagination supplies the phantasm of a former experience, and memory recognizes the phantasm as the representation of an experience had before. Without this recognition, we have the activity of the imagination, but not that of memory. However, for the sake of convenience, it may not always be necessary to make too close a distinction between the reproductive activity of the imagination and the recognitive activity of memory.

There are *two main features* to memorial activity: the recognition of the past, and the estimation and measurement of the past.

Recognition or Remembrance. By this is meant the apprehension of the sameness of two representations or perceptions, one present and one past. I am aware that my present representation or perception is identical with a

representation or perception which I have had on a former occasion.

It may be a question of two perceptions, as when I see a traffic policeman on a corner and remember that I had seen him there yesterday. Or, of two representations (phantasms), as when I imagine Times Square in New York and then remember that I also imagined it last week. Or, of a perception and a representation, as when I see a friend and then remember that I had thought of him (imagined him) only an hour ago. Or, of a representation and a perception, as when I imagine the Old Faithful geyser and remember that I had seen it a number of years ago. These are instances of recognition or remembrance, and the past and present are always linked together.

Mere knowledge of the sameness between one thing and its representation is not sufficient to classify this knowledge as 'remembrance.' For example, I visit a man in his home and I see, let us say, his photograph on the mantle-piece while he is conversing with me. Although I perceive the sameness between this man and the man on the photograph, this is an instance of mere knowledge without memory, because both perceptions occur simultaneously. On the other hand, if I see the man now and recall that I have seen him formerly. it is a case of memory and not of mere knowledge.

The objects of memory are always accompanied by a feeling of *familiarity*, of *acquaintanceship*. Oftentimes we see an object or person, or we hear a melody, or we feel a pain; almost immediately the object, person, melody, pain, etc., seems familiar to us, as if we had had the experience

before. A little effort may recall the exact occasion of the former experience, and then the act of memory is complete. It may happen, though, that no amount of effort enables us to recall the occasion; while it is possible that we may be mistaken concerning the fact of a former experience, this 'familiarity' probably indicates a confused and vague remembrance.

Estimation and Measurement of the Past. It is a fact of everyday occurrence that we *date* and *localize* our experiences in memory by placing them at a definite point in the chain of events reaching into the past; and it is a further fact that we concretely *measure* the time when the past experience took place. How is this estimation and measurement accomplished?

The *psychological process* is as follows. The stimulations of the external senses and the perceptions of the central sense occur successively, so that we have a series of internal conscious states following one after the other. We can gauge the slowness or rapidity of the flow of our internal acts by the rhythmic movements of the breathing of the lungs or of the beating of the heart. We thereby possess a means of estimating and measuring subjective time in a concrete manner. By using this standard of *subjective time* we can now estimate and measure the objective time involved in the sensations and perceptions of objects. The succession of events as we perceived them is fixed according to a 'before' and 'after' in the very series itself. If we now represent to ourselves this internal series of perceptual events, from the present backwards, we not only apprehend 'time' and the 'duration' of time concretely, but

we are able to 'date' and 'localize' a particular event by placing it at a definite point in the series of past events. Certain external events in this series, such as night and day and the annual seasons, stand out in strong relief and become fixed points for dating other events. In this manner we become accustomed to using subjective and objective time for dating and localizing events in memory.

Brutes, too, possess memory. A dog remembers the location of his kennel, recognizes his master, and knows what to do or not to do at a certain command. A delivery-wagon horse remembers all the stops on his regular route. Pigeons remember the cote to which they belong. Bees roam far afield, but they return unerringly to their own hive. Robins discover a cherry tree or a strawberry patch and always find their way back. The training of animals is based on the fact of their being able to remember a certain sequence of actions. Many of the conditioned reflexes induced in the animal experiments of Pavlov and others would be impossible, if the animals had no memory.

Animals have also a concrete estimation of time. The cattle on the farm wend their way to the barn when milking time arrives. Some dogs will stand at the gate every evening at the same time, awaiting the master's return from work. Pigeons remember their regular feeding time and congregate accordingly. In the salivary conditioned-reflex experiments, if the routine calls for food to be given one minute after the signal, the animal remembers the time interval, and salivation does not start until toward the end of the interval. Such instances and experiments prove that animals have memory and estimation of time.

In all that has been said here about time and its estimation, it should be noted that it is the sensory memory that is involved. The abstract concept of time is an object of intellectual insight and is treated in cosmology.²

Learning

In as much as retention and recall play such a predominant role in remembering and forgetting, psychologists have conducted numerous experiments in memorizing, hoping thereby to obtain a better understanding of the inner workings of memory. Many interesting facts have been brought to light by the various methods employed. It would serve no useful purpose to give a detailed description of these methods and their results, but a few of the outstanding facts will be recorded. Unfortunately, most experimenters fail to make a distinction between sensory and intellectual memory, and in consequence materials of both the sensory and intellectual type are used rather indiscriminately, so that it is practically impossible to restrict ourselves here to the data of sensory memory.

In order to test the ability of memory experimentally, something must be 'learned.' Then it is possible to examine how much of the material is remembered and in what manner it is retained, and a statistical score of successes and failures can be established. A number of variable factors enter into the problem of learning: the quantity and quality of the material, the time of learning and other circumstances. These items should make a difference, and they do.

One thing discovered very early in all experiments is the fact of *individual differences*. Memory is not a mechanical device, and not everyone reacts to the same learning methods in the same way. Some persons have a better memory than others. It is in the last analysis a native endowment, dependent on the individual's psycho-physiological organism. To offset these individual differences, psychologists use groups of approximately the same age, educational background, etc., in order to strike a fair average in their experiments. In this connection it is worthy to note that the power of memory shows no marked difference in the *two sexes*. With respect to age, young persons in childhood and adolescence are more adept in word and rote learning, but less adept in learning material according to its intellectual content; the reverse is true of adults. In youth the imagination develops rapidly, while the intellect develops more slowly, due to the fact that the intellect must obtain its data from the central sense and imagination. Adults, therefore, neglect the practice of word and rote learning in favor of memorizing facts and their intelligible relations. Memory is at its best in the years from twenty to thirty, and from then on the curve of learning declines steadily but slightly until far into middle age. Continuous practice will keep the learning curve at a fairly even level until almost into old age. Memory becomes poor in old age because of the general deterioration of the organism as a whole.

In experiments with the *quantity* of material to be learned, the usual procedure is to have the subject read a list of numbers or nonsense syllables and then observe how

many items he can repeat after one presentation. The amount of material remembered after a single presentation is an index of the 'memory span.' No matter what methods or materials are used, there is a *natural limitation* in the amount that can be absorbed by the memory at a given time. This limitation is in all probability due to the fact that after a while the refractory phase of neural activity begins to show its effect.

The *quality* of the material used makes a great difference in learning. Meaningful material is more easily learned than meaningless material. It is possible to connect meaningful words mentally through associative bonds, so that one word will recall the other. It is much more difficult to memorize a list of nonsense syllables like 'zut,' 'koq,' 'gif,' etc., than it is to memorize meaningful words like 'rose,' 'foot,' 'here,' etc., because nonsense syllables must be learned by a sheer act of memory without aid from natural or artificial associations. Due to this fact, memory, as memory, can be tested much better in its power of retention and recall by means of nonsense syllables and numbers.

The *time* element also makes a difference. Given the same quantity and quality of material to be learned, it makes a difference whether five minutes or thirty minutes are given to memorize a lesson. A longer period, with the possibility of repeating the learning process, gives the memory trace a better chance to become set and fixed in its character. Similarly, if the material is allowed to be 'relearned' after an idle period of retention, memory can be tested by noting the 'time saved' in rehearsing as compared to the time required for the first learning. The memory

trace is strengthened considerably by relearning, and recall is facilitated. This *spaced practice*, as it is termed, is of considerable importance in learning extensive material. The periods between relearning should be filled out with a totally different occupation, in order to obtain best results. 'Cramming' is a poor method of learning. The neural mechanism, after a period of protracted activity, always needs time for rest and recuperation; it cannot be active without the expenditure of nerve energy, and this energy is limited in amount. The refractory phase sets in, and the nerves demand a period of relative inactivity. To continue the memorizing of the same material during the refractory phase of nerve activity is not only harmful to the nerves themselves, but does not help the task of memorizing. After a certain span of time, which naturally differs with different individuals, a point is reached where the memory is saturated and can absorb no more.

The period of rest consists in some form of relaxation for the particular set of cortical centers used in the previous task of memorizing. Just what the form of relaxation happens to be, is of minor importance. Experiments, however, show that the best method is to apply one's self to the memorizing of a task just before retiring at night, provided one is not too fatigued, and then relearn it in the morning. The traces of the phantasms impressed upon the nervous elements thus have a better chance to become strengthened. This strengthening of the traces is probably due to the *perseveration* tendency of images, namely, the tendency of images to reappear soon again in

consciousness. We are confronted with a curious phenomenon of the retention of images, reminiscence.

Reminiscence

By *reminiscence* is meant the spontaneous and gradual improvement of memory with a subsequent higher score in recall, without a relearning or rehearsal of the memorized material.

If true, we face a paradoxical situation. It is a known fact, of course, that we usually do not retain and remember all we attempt to learn. It is also a known fact that memory images fade rapidly after learning, so that the ability to revive them deteriorates as time progresses unless reinforced by relearning and rehearsal. Reminiscence would be the opposite. It implies that the memory traces, if left to themselves during a period of mental incubation, are not inactive, but pass through a stage of latent organization and of gradual development in the subconscious recesses of the mind.

Certain *experiences* apparently indicate that there is a rhythmic character to the memory curve, a waxing and waning of the memory trace. According to this view, spaced learning and perseveration would receive a neat explanation. Perseveration is a fact. Images have a tendency to crowd up to the level of consciousness not long after the original experience. We hear a striking melody; and the melody continues to haunt us for hours, periodically running through our mind. Things we have heard or seen float in and out of consciousness in a sort of rhythmic

succession, at least for a time. In spaced learning, as we know, we can memorize more material and are able to recall this material more effectively than if we used the same amount of time in a single span of learning. It would seem that the curve of retention is like a wave, with crests and troughs; when the period of relearning coincides with the crest of subconscious memory activity, the traces are reinforced and thereby strengthened.

The 'inspiration' of genius lends color to this theory of reminiscence. The biographies of great artists narrate many instances where an artistic theme, left dormant for a while, suddenly flashed through their mind with the perfection of a completed product. It was as if the imaginative power or, if we wish, memory worked subconsciously on the theme and, without interference or aid from any conscious course, brought it to fruition. A stubborn problem is often best solved by laying it aside for a period of time and then taking it up again. Oftentimes, too, when a name or word eludes all efforts at recall, we brush the whole matter aside and occupy our mind with something else; sometime later, and quite suddenly, the desired name or word will probably burst upon consciousness. Do such experiences prove the fact of 'reminiscence,' so that a spontaneous and gradual consolidation of memory traces actually occurs in the workshop of the subconscious mind? The professional psychologists have taken up the problem.

Experiments have been made in an effort to prove or disprove the alleged phenomenon of reminiscence. The method used was to have subjects learn a memory task.

Tests consisted in comparing the results of immediate recall and delayed recalls, the subjects being kept in ignorance of the fact that delayed recalls were to be made. Philip Ballard (1913) undertook a large number of experiments with school children. Taking the score of the immediate recall as 100, he found their average score after one day to be 111, after two days to be 117, after three days to be 113, after four days to be 112; and from there on the score dropped gradually. Nicolai (1922), exposing a box of assorted toys to children, also found that their average score of recall had risen from 5.4 objects to 6.3 in one hour, and to 7.8 in twenty-four hours; even after four weeks their average score was 7.4. Nicolai was certain that no rehearsal had been possible at least for the first hour, because their time during this hour had been filled out with school work. Welborn and Killiam (1934) made tests with college students. In the tests the memorized material was presented to the students in two forms; some sentences were presented verbatim, while other sentences were presented according to the substance of the subject matter. Tests of verbatim items after 10 minutes and after 30 days showed a score of 37.7 and 33.5 respectively; tests of substance items for the same intervals were 19.1 and 26.9 respectively.

On the other hand, experiments made by Williams (1926), Warner Brown (1923), Raffel (1934), and others, show no latent consolidation and improvement. Woodworth³ is convinced that the facts can be explained by chance recall and by the 'condition of readiness,' and there is no need to have recourse to 'reminiscence.'

The problem is admittedly a thorny one. Since the process of recall itself is not open to inspection, the only available method is that of the recall score. This method would be good, if it were possible to exclude all rehearsal on the part of the subjects. It is not a question of deliberate rehearsal on their part, but of sporadic, intermittent rehearsal of a casual sort; the subjects may just 'think about it' off and on between tests, without even realizing that this amounts actually to rehearsing. A control over this kind of indirect review of the memorized material is next to impossible. Following this line of thought, G. O. McGeoch (1935) made experiments with school children. After the tests, upon her inquiry, it was discovered that approximately 77 per cent admitted some rehearsal; oddly enough, though, the recall score of those who did not review the material also showed improvement.

And so opinions differ. The controversy is not settled. Experiments are still being conducted, to determine, if possible, the exact nature of the phenomenon.

Retroactive Inhibition

Psychologists understand by *retroactive inhibition* the tendency of mental activity to impair the recall of memorized material, if this activity is placed between the time of learning and the time of recall. The term 'retroactive inhibition' is open to misinterpretation. The expression might be understood to mean that such an activity is 'retroactive' in the sense that the effect of its influence reaches back into the past beyond the point of

time when the activity itself, as the cause, actually occurred. Such a view would be equivalent to the statement that the effect is prior to its producing cause — a patent impossibility. Psychologists, of course, do not attach such a meaning to the term. What they intend to imply is, that mental activity, interpolated between learning and recall, *interferes* in some manner with the recall of previously memorized material; in other words, such an interpolated activity has the tendency to make us forget what has been learned immediately before.

The *fact* itself is certain. Common experience shows that best results in memorizing are obtained, if a period of rest follows the period of learning; the results are not so good, if the period of learning is followed by strenuous mental activity of the same or of a similar kind. Psychologists observed the same fact in their psychological research work on memory.

Since the turn of the century, many *experiments* have been made to determine the character of retroactive inhibition. Muller and Pilzecker (1900) had observed that recall after a period of idleness was more than 50 per cent better than when learning was immediately followed by intense mental activity. Muller and Pilzecker were the first to call attention to the phenomenon of 'perseveration,' and they interpreted this perseveration as a consolidation of the memory traces, so that the traces have the natural tendency to re-occur in consciousness for a time. Retroactive inhibition, then, would hinder this consolidation of the memory traces, in as much as intense mental activity, following a period of learning, would hinder the original

traces from going through their normal phase of consolidation. Viewed this way, retroactive inhibition is a form of *anti-consolidation*.

While not all psychologists agree with the Muller and Pilzecker theory of anti-consolidation, their experiments confirm the fact of retroactive inhibition in general. It was found, however, that the retroactive inhibition of interpolated mental activity depends on the *type of activity* to a great extent. Retroactive inhibition is strongest when the interpolated *material* is rather *similar in form*, though of a *different content*, to the original material memorized. When the interpolated material is of a markedly different character, inhibition is not so pronounced; but any type of strenuous mental activity exerts an inhibitory effect in some degree. The same situation prevails when the mental operations are similar or dissimilar in type. Quite naturally, retroactive inhibition will be strongest when both material and operation are similar to, and weakest when material and operation are dissimilar to, the material and operation found in the original task of learning. Experiments were made along these lines by Robinson (1920), Skaggs (1925), McGeoch and McDonald (1931), Nagge (1935), and others. All revealed the fact that retroactive inhibition occurs, but they do not seem to confirm the theory of anti-consolidation as propounded by Muller and Pilzecker. Muller and Pilzecker maintained that the factor in retroactive inhibition which hindered the consolidation of the memory traces was the *strenuousness* of the interpolated mental activity. Were the 'strenuousness' the factor, the similarity or dissimilarity of the interpolated material or operation, with respect to

the material and operation of the original task, should not influence the recall one way or the other; so long as the interpolated activity is not strenuous, consolidation of the traces and subsequent recall should proceed normally. These more recent experiments, however, show plainly that *similarity of form* in the material and operation is the disturbing factor in retroactive inhibition, even though perhaps not exclusively.

There is a further point to consider. In the anti-consolidation theory of Muller and Pilzecker the *time element* seems essential. In order that the traces can consolidate properly, a period of relative rest should follow immediately after the period of original learning. Given this period of rest for consolidation, retroactive inhibition should not occur. But it does occur. Muller and Pilzecker found that even a brief pause after learning eliminated the effect of retroactive inhibition to a large extent. On the other hand, Robinson (1920) and McGeoch (1933) found that any activity interpolated between learning and recall, whether at the beginning or middle or end of the interval, brought on retroactive inhibition. Whitely (1927) and von Restorif (1933) maintain that inhibition will take place and diminish recall, if the mental activity immediately precedes the original memory task instead of being interpolated between learning and recall; such an inhibition would be proactive, not retroactive.

In view of these findings, some psychologists prefer the *transfer or interference* theory of DeCamp (1915) and Webb (1917) to the anti-consolidation theory of Muller and Pilzecker. According to the transfer theory, the original and

interpolated activities intermingle, so that the two sets of traces become a single mixed set with subsequent confusion of recall results, or the traces of the original material are used with the traces of the interpolated material and become modified thereby.

It is questionable whether the anti-consolidation and the transfer theories are strictly antagonistic and exclusive. The facts seem compatible with both theories. Muller and Pilzecker may have been mistaken in ascribing restrictively the effect of retroactive inhibition to the 'strenuousness' of the activity interpolated immediately after the period of original learning; however, the facts brought to light in the experiments of recent years do not necessarily rule out the possibility of a consolidation of the traces. Both the transfer theory and the anti-consolidation theory are plausible interpretations of the facts discovered, but each may possibly be only a partial interpretation of all the facts involved. Further investigation is still needed.

If we now turn our attention to the familiar phenomenon of *forgetting*, we find that normal forgetting is accounted for by two main factors. The first is the *natural fading* of the memory trace. Unless an experience is recalled from time to time, so that the trace is strengthened and made ready for further recall by associative bonds of some sort, the lapse of time makes the trace weaker and less capable of recall. It is a question, however, whether the trace is ever completely obliterated, because sometimes past events, long forgotten, are recalled with a startling vividness of detail. The second factor is the effect of proactive and retroactive *inhibition* on the part of interfering mental

activity. The present discussion brings out this point. Proper methods of memorizing will retard the negative process of forgetting by furnishing aids toward the consolidation and strengthening of the traces.

Recall and Recognition

Recall is the mental reproduction of a former stimulus or experience. Recall, of course, is dependent on the trace left by the former stimulus or experience. If this trace should have become obliterated for some reason, recall is impossible; if the trace is still present, no matter in how strong or weak a condition, recall is, theoretically at least, always possible.

Recognition is the consciousness that the stimulus or experience now present has been present formerly. It also is dependent on the trace left by the former stimulus or experience. If this trace were obliterated, recognition would be impossible; the present stimulus or experience would indeed be the repetition of a former stimulus or experience, but it would not be 'recognized' or 'remembered' as such and would simply be considered as being present for the first time. The same trace, therefore, is active in both recall and recognition.

It would be erroneous, however, to judge from their mutual dependence on the memory trace that the functions of recall and recognition are identical and to state, as Stevenson Smith (1927) does, that there is no definite difference between them. Mutual dependence on something does not necessarily mean identity.

The facts show that recall and recognition are *distinct functions*. We can have recall without recognition, and we can have recognition without recall. Consider the following experiment. A subject is made to memorize a list of 50 meaningful words. After two days he is told to write a list of 50 words, including in this list all the words of the original list which he remembers; he is then requested to make a check mark back of the words which he recognizes as having been on the original list. On comparing the two lists, we find the following (here, of course, hypothetical) results: 20 correctly checked words, recalled and recognized; 30 unchecked words, supposedly not on the original list. Upon examination, however, we find 20 entirely new words among the unchecked words and 10 of the original list; these 10 were, therefore, recalled but not recognized. The score: recall, 60 per cent; recognition, 40 per cent. In actual experiments the results will, in all probability, be somewhat different; but something of the sort usually happens, showing that more items are recalled than are recognized. And if the remaining 20 unrecalled and unrecognized words of the original list are now mixed with 30 new words, so that a new list of 50 words is presented to the subject, he will, in all probability, be able to pick out a fair number of words which he now recognizes as having been on the original list, though they were not recalled in his test list. Here, then, we have recognition without recall, while in the test we had recall without recognition and also recall with recognition.

Everyday experience confirms these findings. We sometimes have recall without recognition. In an idle

moment of relaxation we may hum what we think is a spontaneous melody of our own composition. Later on, we hear an orchestra on the radio play a piece which contains the main features of this melody. We had most probably heard the melody on a former occasion and recalled parts of it, though we had not recognized it as a previous experience. It happens, too, that authors are guilty of what may be called 'unconscious plagiarism.' They read something striking, and it makes an impression; but they soon 'forget' all about it. At a future date, they have occasion to write on this particular subject. Among the matter written may be found a few sentences which, as a matter of fact, are practically verbatim repetitions of what they had read formerly, although they are unaware of this fact; it is an instance of recall, but not of recognition. The reverse is also true. Somebody speaks to me of a person who is supposed to be a mutual acquaintance; he may relate place, date, incident, conversation, etc., but to no avail. Upon showing me a snapshot of the person, I now recognize him, though up to that moment recall was impossible. It often happens, too, that we cannot recall a certain song or orchestral composition; but we have immediate recognition of it, when we hear it again.

Recognition without recall is a very frequent occurrence in memorizing, let us say, a lengthy poem or an address. After having read it over a few times, we will be able to recall some parts of the poem or address, but most of it we cannot recall. When, however, we glance over the poem or address for relearning, we experience no difficulty in recognizing it in its entirety. The trace is present, but too

weak to be activated into full recall; the item itself, though, when presented, is readily recognized as having been presented before.

We thus come to the conclusion that recall and recognition are distinct functions. Were they identical operations, the presence of the one would of necessity involve the presence of the other. When the one can be present and the other absent, they must be diverse operations.

There are a number of *characteristic differences* which mark off recognition from recall. They show that recognition and recall are not identical functions. T. V. Moore⁴ enumerates the main ones.

Complexity of detail in the original stimulus creates a greater difficulty for recall than it does for recognition. The details of a poem, for example, may be incapable of recall after a single reading, but their recognition should be an easy matter. A musician may not be able to recall the details of a musical score after hearing it for the first time, but he probably would have little difficulty in recognizing the piece when hearing it again. Increasing the number of words in a test makes recall more difficult, but the recognition of the list itself is made scarcely more difficult on that account. A mechanic may find considerable difficulty in recalling all the parts of a complicated machine, but he recognizes each part when he sees it. Children are often unable to recall the exact spelling of lengthy words, but they recognize the words when reading.

Recall is affected more adversely by *retroactive inhibition* than is recognition. Strenuous mental activity,

following immediately after a memory task, interferes with the recall of the contents of this task but it does not interfere with recognition. The memorizing of two poems in succession, similar to each other, brings on retroactive inhibition, and recall is thereby impaired; but it does not impair the recognition of the poems. A lesson in Italian, succeeding a lesson in Latin, induces retroactive inhibition, because of the similarity of form existing in the two lessons; recall is impeded, but recognition remains relatively intact.

Primacy and recency influence recall more than they do recognition. When memorizing a series of items, such as a list of words, syllables, or numbers, it has been found that the first and last items of the series, all things being equal, are retained better and can be recalled easier than the middle items of the same series. The earliest (first, primary) and the most recent efforts in learning have an advantage, so far as retention and recall are concerned, over the efforts which occur in between. The fact itself is beyond dispute. Psychologists offer the following explanation. The beginning of a series receives full attention, because nothing precedes it; hence, the impression of the memory trace is deeper and stronger. The memory trace of the middle of the series is interfered with by the proactive inhibition of the first part of the series and by the retroactive inhibition of the last part of the series. The last part of the series is not interfered with by retroactive inhibition, because nothing follows it. The middle part of the series, no doubt, produces a retroactive inhibition upon the first part and a proactive inhibition upon the last part. But the first and last part of the series thus suffer from only one

factor of inhibition, while the middle part suffers from two factors. Whatever may be the true explanation of the fact, primacy and recency are advantageous for recall. As for recognition of the items of a series, the first and last parts have no advantage over the middle part; all are recognized with equal facility.

A *single rehearsal* makes recall difficult, but not recognition. As a rule, the material, if somewhat extensive, must be rehearsed a number of times before it can be effectively recalled. The recognition of this material, however, is much easier after a single rehearsal than its recall. After a single rehearsal, a subject may recall but a few items from a list of words; when presented with the words, however, the subject will readily recognize many more words as present in the list than those which he was able to recall.

Meaningful material facilitates both recall and recognition, but recognition is affected more than recall. Nonsense syllables are much harder to recall and to recognize than meaningful words. Similarly, memorization, with subsequent recall and recognition, of material in one's native language is far easier than that in an alien language. Obviously, too, the recognition of meaningful material is not as difficult as the recognition of material without meaning.

The *will to remember* is an important factor for recall and recognition, but more important for recall than for recognition. Since recall is a more difficult operation than recognition, the will to remember naturally benefits recall more than recognition.

These facts prove that recall and recognition are distinct functions. In ordinary conversation we seldom make the distinction, using both terms indiscriminately, but the distinction is there and should not be overlooked.

Pathology and Memory

Pathological disturbances of memory throw the functions of retention and recall into high relief. The causes of such disturbance may be either organic or psychogenic. The *organic* causes involve a destruction or impairment of cerebral nerve tissue, due to injuries (a fall, a head wound, etc.), disease (syphilis, etc.), poisoning (alcohol, carbon monoxide, etc.), and similar agencies. The *psychogenic* or mental causes involve a functional impairment, due to excessive mental strain, emotional shock, hysteria, and so forth. The resultant amnesia differs in the two types of cases. In the cases where organic factors are the cause, amnesia takes the form of inability to store new impressions, while the power to recall impressions stored prior to the onset of the cause remains relatively intact. In the cases where psychogenic factors are the cause, amnesia takes the form of inability to recall impressions of the past, but the power to store new impressions following the onset of the cause remains relatively intact. At times, of course, both organic and psychogenic causes are involved, and in such cases the impairment of memory is more pronounced and general in character. Psychogenic amnesia usually clears up rapidly of its own account. Organic amnesia is not so amenable to treatment and cure, especially where

cerebral lesions have occurred; where poisoning is the cause, the elimination of the poison frequently leads to partial or complete restoration of memory. Psychogenic amnesia is more in the nature of retroactive inhibition, while organic amnesia is more in the nature of a partial or total inability of the memory traces to register, due to the partial or total destruction of a section of nerve tissue itself.

It is thus clear that retention, recall, and recognition are distinct functions. It is also clear that the imagination cannot function in the absence of an object without retention and recall. Either, then, imagination and memory are parallel powers, both utilizing the same material through retention and recall; or retention and recall should be assigned to imagination, leaving recognition and the estimation of time as the proper functions of memory. The latter view seems preferable.

Summary of Chapter IX

Memory is one of the internal senses.

1. *The Concept of Memory.* By sensory memory we understand the power to recall past objects and states of consciousness and recognize them as having been present in former experiences. The distinctive element of memory is the recognition of past objects and events, not their retention and reproduction. The two main features of memorial activity are the recognition of the past and the estimation or measurement of the past.

Recognition or remembrance is the apprehension of the same-ness of two representations or perceptions, one present and one past. By the *estimation* and *measurement* of the past we mean that we date and localize our experiences in memory by placing them at a definite point in the chain of events reaching into the past and concretely measure the time when the past experience took place. *Brutes* also possess memory in these two features.

2. *Learning.* Experiments in learning reveal how much of the memorized material is remembered and in what manner it is retained. There are a number of variable factors which enter into the problem of learning: the quantity and quality of the material, the time of learning, and other circumstances. Generally speaking, 'spaced learning' is the best method of memorizing; this fact is probably due to the perseveration tendency of images.

3. *Reminiscence.* By this is meant the spontaneous and gradual improvement of memory with a subsequent higher

score in recall, without a relearning or rehearsal of the memorized material. It implies that the memory traces, if left to themselves during a period of mental incubation, are not inactive, but pass through a stage of latent organization and of gradual development in the subconscious recesses of the mind. Opinions differ with regard to the existence of reminiscence.

4. *Retroactive Inhibition*. By this term psychologists understand the tendency of mental activity to impair the recall of memorized material, if this activity is placed between the time of learning and the time of recall. The fact itself is certain, as proved by common experience and by psychological experiments. Retroactive inhibition is strongest, when the interpolated material is similar in form, though of different content, to the original material memorized; it also occurs when the mental operations of the interpolated activity are similar to those of the original task.

Muller and Pilzecker have advanced the theory that the strenuousness of interpolated activity hinders the consolidation of the memory trace. Their theory is the *anti-consolidation* theory of retroactive inhibition. Many psychologists prefer the *transfer or interference theory* of DeCamp and Webb. According to this theory, the interpolated and original traces become a single mixed set, or the traces of the original material are used with the traces of the interpolated material and become modified thereby.

Forgetting is due either to the natural fading of the memory trace or to proactive and retroactive inhibition.

5. *Recall and 'Recognition*. They are distinct functions. We can have recall without recognition, and recognition without recall. If they were identical, the presence of the one would involve the presence of the other. There are a number of *characteristic differences* between recall and recognition.

6. *Pathology and Memory*. The causes of the pathological disturbances of memory are either organic or psychogenic. The former involve a destruction or impairment of cerebral nerve tissue, due to injuries, disease, poisoning, and similar agencies. The latter involve a functional impairment, due to excessive mental strain, emotional shock, hysteria, and so forth. Organic amnesia takes the form of inability to store new impressions, while the power to recall impressions stored prior to the onset of the cause remains relatively intact. *Psychogenic amnesia* takes the form of inability to recall impressions of the past, but the power to store new impressions following the onset of the cause remains relatively intact.

Retention, recall, and recognition are distinct functions. It seems preferable to assign retention and recall to imagination and consider recognition and the estimation of time as the proper functions of memory.

Chapter 10

INSTINCT

SO FAR WE HAVE EXAMINED THE EXTERNAL SENSES AND THREE OF the four internal senses.

The purpose of the entire process of sensory knowledge is to make us acquainted with ourselves and with the objects of the external world, so that we may be able to adjust ourselves to our environment in accordance with the needs of our *well-being* as individuals and as members of a species. The individual must live, and the race must survive; that is the law of nature. In brutes and men the knowledge acquired

by the senses must serve the ultimate demands of the well-being of the individual and of the species. Knowledge thus acquired, however, is insufficient to achieve the realization of the well-being of the animal organism in all its necessary phases. This realization is achieved to a great extent through the activity of the fourth and last of the internal senses — *instinct*.

The Concept of Instinct

The term *instinct* (Lat., *instinguere*, to incite, to goad) connotes a drive, an urge, an *impulse to action*, analogous to the prodding of an animal by a goad or spur, urging it to move forward toward a goal. The term designates the impulsive tendency toward actions which are conducive to the *well-being* of the individual or of the species, either by attaining what is good and useful or by avoiding what is evil and harmful. The term also implies that the impulse to such actions is a *native endowment* of the organism, independent of whether or not the individual has a 'logical understanding' of the purposiveness of such actions or of the good to be attained and of the evil to be avoided. Finally, the term is usually employed to designate the impulse to a definite set of actions serving the well-being of the individual or the species prior to any learning by experience on the part of the individual performing the actions.

Besides this dynamic element in instinct, there is also the *cognitive element*. Even though the term 'instinct,' as commonly used, is viewed primarily as referring to action, instinct does not exclude knowledge. As a rule, and perhaps always, men and animals acting instinctively are aware of their actions, even if they are not aware of the 'why and wherefore' of such actions; they know what they are doing when they do it, though the 'reasons' for their action may be little understood or not understood at all.

Such is the general concept of 'instinct' in popular parlance. This concept is sufficient as an approach to the internal sense under discussion. How far this concept is justified, will become clearer at the end of our investigation.

The Existence of Instinct

In order to determine whether such a thing as instinct exists, the behavior either of men or of animals can serve us as a guide in our investigation. In the case of human behavior we have the advantage of introspection; but we also have the disadvantage that intellectual activity controls our actions to such a degree that it is difficult to discern where instinct ends and intellect begins or how far they intermingle. In the case of animal behavior we have the advantage that we know that intellect plays no part in the action; but we also have the disadvantage that we can arrive at a knowledge of the mentality of the animal only by inference and not by direct observation. Instinct, if it exists, will certainly appear in a purer and clearer form in animals than in men, because of the fact, as we will see later, that they are not influenced by an intellect and will. For this reason it is customary to base the study of instinct more on the actions of animals than of men.

Animal behavior manifests instinct.

A few typical cases will show conclusively that animals possess an *innate impulse, antecedent to all individual experience*, determining them to certain *uniform, purposive actions, useful for the individual and the species*.

Animals perform some actions in virtue of an *innate impulse*, prior to experience. Flourens narrates the incident of a beaver that was captured soon after birth and placed in the Jardin des Plants in Paris, where it was reared in a cage. When the beaver was fully grown, an experiment was tried with the animal. Soil, twigs, and water were placed at its

disposal. The beaver, although in no need of a hut, went to work without any hesitation and built the typical hut of its species. This beaver had never seen a beaver hut and could not have learned the plan and principles of construction from its parents nor from individual experience. What is the explanation? Only one explanation is possible: upon sight of the building material it had the impulse, fixed in its nature, to build a hut in a definite way according to a definite plan, and the typical beaver hut was the result.

Another example. W. S. Ritter placed a number of trap-door spiders, as soon as they were hatched, in a dish containing moist earth. Though still immature, each spider began its nest according to the standard pattern of the nest made by the mature spiders, only smaller in size so as to fit the size of its immature body. The lid or trap door of such a nest is a most ingenious contrivance, and the little spiders fashioned the lids with utmost nicety and skill, although they had never seen a nest and could not have learned the procedure from any other spider. Here again we observe a sequence of actions which manifest an innate impulse, independent of any prior experience.

Birds, even when reared in a cage from the time they are hatched, will always, when liberated, build a nest of the same material and pattern as the other birds of the same kind, although they have never seen a nest built. Spiders, too, will spin the typical web of their species, without ever having seen a web or the spinning of a web. Ducklings will take to water and swim, immediately after they have been hatched. The leaf-roller insect will construct its nest in a leaf, thereby solving incidentally a most intricate problem of

geometry, under circumstances which preclude the possibility of learning by experience or in any other manner. The life history of animals is replete with instinctive actions which manifest innate impulses.

That such actions are the result of an *impulse*, and not of a rational understanding of their purposiveness, should be equally clear. If they were due to intellectual insight or a process of reasoning, one would be constrained to place animals on a higher mental plane than man, because some of these actions, always performed unerringly and unfalteringly, are eminently purposive in character and highly ingenious in pattern. Man could not solve some of the problems involved in such actions without considerable study and preliminary education. Notwithstanding the ingenuity displayed in instinctive behavior, animals reveal no signs of genuine intellectual insight. On the contrary, the behavior of animals shows that they have an almost irresistible 'drive' to perform a determined set of actions, but have no 'understanding' of the intrinsic reasonableness of their actions.

The action of the beaver mentioned above manifests an impulse, but no understanding, because it had not use for a hut under the circumstances. H. Fabre, the eminent French naturalist, narrates many incidents of animal behavior which reveal phenomenal mental obtuseness in what is otherwise an apparently highly intelligent performance. On one occasion he experimented with a *sphex*, a type of solitary wasp. This particular type stored grasshoppers in an excavated nest as food for its young. The routine is as follows: the *sphex* brings the grasshopper to the rim of the

nest, enters the nest to explore its condition, returns to the top, and then drags the grasshopper into the nest. While the wasp was exploring the interior of the nest, Fabre removed the grasshopper a short distance; the wasp, returning to the top, saw the grasshopper, brought it back to the rim of the nest, and went to explore the interior once more, although it had done so only a moment before. Fabre repeated the experiment over and over, always with the same results. This behavior on the part of the wasp shows an impulse to perform a certain set of actions according to a definite plan, but it also shows a complete lack of understanding of the purpose of the plan. On another occasion, Fabre made an experiment with a honey bee. The bee is to all appearances a very intellectual insect, since it solves a logarithmic problem in the construction of its cell. Fabre wished to test the mental insight of the bee. A bee had already partially filled a cell with honey. He pierced the bottom of the cell, so that the honey flowed away. The bee continued to put honey into the cell and add wax material to the walls. The bee made thirty-two trips, collecting honey and building material, but not once did it occur to the bee to investigate why the cell was always empty of honey. Impulse was present, but no reason or intellectual insight.

Instinctive actions are eminently purposive in themselves, but the animal performing them evidently carries them out because of an impulsive drive and not because of any understanding of their aptness. Whenever unusual circumstances break the routine of the sequence or frustrate its purpose, the impulse still persists, and the animal attempts to carry the action through to its normal

conclusion, although the continuance of the action can serve no useful purpose.

While animals possess a certain amount of individuality and adaptability in instinctive actions, as will be pointed out a little later, their actions always follow a definite *uniformity* of pattern. Each kind of bird builds its nest in the same fashion and of the same general materials as the rest of its kind; this characteristic can be observed in the swallow, the sparrow, the canary, the woodpecker, the wren, the ostrich, the eagle, etc. Bees build their cells alike the world over. Rabbits, woodchucks, gophers, chipmunks, moles, foxes, etc., make their burrows in the same way as their fellows. The wolf, the cat, the dog, the lion, the tiger, the otter, etc. — all hunt according to the method of their type and that uniformly. There is no tendency on the part of the animal to improve on the method of its action or to use other means to accomplish the same end; the course of the action is set, and the animal runs faithfully through the course.

Instinctive actions are not random performances, but purposive. Some involve a marvelous complexity of coordinated movements, occupying a considerable length of time. When it is stated that instinct drives to 'purposive' actions, this simply means that these actions are, as a matter of observable fact, *purposive in themselves*, adapted as means toward the realization of a definite end or goal.

IF WE SEEK THIS PURPOSE, WE FIND THAT IT CONSISTS IN THE *well-being* of the individual and of the species.

As for the well-being of the *individual*, all the instincts governing the search for food and self-defense belong to this category. Animals know instinctively what foods are good or harmful for them, and they know just how to go about acquiring the food they need. This instinct is more specialized in some animals than in others. Some types of birds will starve to death, if their particular kind of food has been destroyed through a wide area, even though the food of other birds or animals be present in abundance. As for self-defense, each class of animals has its own method of defense in time of danger, and the members of each species react to danger in the same general way. To quote Muckermann: "For what other reason but to seek protection from danger do worms contract the segments of their body, hedgehogs roll themselves into balls bristling with spikes, snails retire into their shells, turtles withdraw their heads and legs and hide themselves in the sand, young snakes jump into the mouth of their parent, chickens seek protection under the wings of the hen?" The fact of general uniformity in the actions of the members of the same species shows that such behavior is instinctive.

The technique required for the well-being and *preservation of the species* is never learned by the individual animal. Whatever may be the process of reproduction, sexual or asexual, the perpetuation of the species is maintained by a sequence of wonderfully coordinated actions directed toward this end in virtue of an instinct rooted in the inmost nature of the animal, and this instinct cannot be denied. To quote Muckermann again: "Nor can any other explanation than 'purpose' be given for

those actions by which animals preserve their species. Or why do they always deposit their eggs in places which offer the most suitable food for their offspring? Why do mosquitoes drop their eggs into water, the only place where the young can develop, cabbage-butterflies deposit them on the under side of the cabbage leaf, *sitaris* in the nest-entrance of *Antophoras*? Why does the fly *Gastrus equi* paste them on the breast of a horse, where they are licked up by the horse's tongue and forwarded into the stomach, the only place where the maggots find their specific and necessary nourishment? Why do several species of solitary wasps fasten their eggs on the bodies of living but paralyzed spiders, caterpillars, and grasshoppers? Why does the great water-scavenger, *Hydrophilus piceus* build a little boat for its eggs, and *Lochemusa*, *Xenodusa*, *Atemeles* . . . bring them into the nest of ants; why in short, does every species find those places and conditions which are best adapted to secure the welfare of its offspring? There can be no question of chance where such a universal experience confronts us with such wonderful facts, and it is consequently evident that a 'purpose' in finding suitable nourishment, in protecting the individual and propagating the species, is an essential constituent of all instinctive actions of animals."¹

Such are some of the facts, taken from among millions, which show the operations of instinct and thereby reveal its nature. Summing up the essential features of instinctive actions, we can now define instinct, with William McDougall, as "*an innate disposition which determines the organism to perceive (to pay attention to) any object of a*

*certain class, and to experience in its presence a certain emotional excitement and an impulse to action which find expression in a specific mode of behavior in relation to that object."*²

Instinct and Experience

In considering instinct, as expressed in the definition just given, one is liable to draw the conclusion that instinctive activities are so stereotype in character as to be beyond the modifying influence of experience. Such a conclusion would be erroneous. Instincts can be *modified* to a certain extent by the experience of the animal.

Some birds use pieces of string, cord, paper, cloth, and similar objects in the construction of their nest. In the beginning these birds could not have been prompted by their instinct to use such artificial products, for the simple reason that the birds made nests before man made such articles. Barn swallows now frequently attach their mud nests to the inside of barns, and chimney swallows to the inside of chimneys. This method of nest-building is a modification of their original instinct, because they certainly built nests long before barns and chimneys existed. Canadian partridges construct a little roof over themselves in Canada, for the purpose of shelter; in a warmer climate they omit the shelter roof. Wrens, sparrows, martins, etc., use birdhouses made by man for nesting purposes. The mud-dauber wasp makes its mud nests in hollow trees and overhanging rocks; but it will also make them in structures built by man.

We thus notice that instinct is not a rigid and uncontrollable automatism, but an innate disposition which possesses a certain amount of plasticity and flexibility, capable of being modified and adapted to the requirements of existing circumstances.

Experience and Intelligence

Animals act by instinct. But not always. They also act by learning through experience. Experiential actions often resemble instinctive actions, in so far as they are purposive in themselves and tend toward a definite goal; they are, however, not the result of an innate disposition or drive, present in the animals antecedent to experience. The sense of well-being prompts animals to act, and so they seek to attain what is good for them and to avoid what is evil; and experience teaches them what is good and what is evil. Experiential actions possess a spontaneity and individuality of expression which is lacking in typically instinctive actions.

Pleasure is a good and pain an evil which animals associate with experiential actions, and thereby they learn to perform or avoid certain kinds of activities. The *training* of animals is based on this general principle. Punishment is meted out to them, if they do something undesired by the trainer or refuse to do something desired by him; a reward is given to them, if they do what the trainer desires or omit to do what he wants them to omit.

Animals, however, can also learn by experience *of their own accord*. A cat which burns her paw at a hot stove will refrain from going near it. A dog, once scratched by a cat,

will be wary of the cat the next time. Animals and birds in isolated regions or in refuge areas show at first no fear of man; but it does not take them long to learn to distinguish between those who are kind to them and those who wish to do them harm. In Yellowstone Park the bear, the bison, the elk, and the mountain goat are relatively tame, because they experience no harsh treatment.

While it is true that the general pattern of the instinctive actions of a species is predetermined and uniform, it is equally true that the details are subject to modification and change. The animal, in many cases at least, adapts its method of searching for food, of defense, of escape, of mating, of parental care, to the changing circumstances of the environment.

HAVE ANIMALS *INTELLIGENCE*?

The question has agitated the minds of psychologists and philosophers for a long time, and a considerable controversy has grown up around the problem. Consider the following facts.

William McDougall relates how his son, K. D. McDougall, experimented with a dauber wasp making a nest of mud cells for her eggs. Oddly enough, the wasp proceeded to attach the cells to a suspended wire. While the wasp was away collecting material to finish a nearly completed cell, McDougall made a hole through the blind-end wall of the cell. The wasp returned with a pellet of clay to build the wall, but saw the hole, fussed around in an agitated manner, and finally began to repair the damage with the

pellet that should have been used to build the upper wall. She brought two more pellets, plugged the hole completely, and then continued to build the rest of the wall where she had left off. A number of experiments of this type, but with variations, were made. The result was the same: the damage was always repaired, but the procedure of repair was different in the different instances. This repair work was certainly not included in the instinctive building schedule of the wasp; yet the wasp rose to the occasion and finished the task, notwithstanding outside interference.

Many laboratory experiments have been conducted with animals. Thorndike's experiments are famous. White rats, for example, were allowed to become very hungry, so as to stimulate their food-seeking instinct. Food was then placed in a box, and the rat had to find its way into the box. The box was so constructed that the rat had to push a lever, pull a string, or perform some other operation, in order to be able to enter. The rat invariably proceeded according to a trial-and-error method. When at last the rat succeeded accidentally in tripping the opening mechanism a few times, it remembered the procedure and from there on went through the proper sequence without fail. In this manner a rat can train itself to operate a number of latches before being able to obtain its food. McDougall made a puzzle food box with fourteen interlocking latches, and a white rat finally learned to master the device. Once such an animal memorizes the sequence, it experiences little trouble in opening the box.

Animals, it will be observed, possess a certain spontaneity and initiative in their actions, so that they are

capable of learning by experience; they can also modify the sequence of instinctive actions in a measure, so as to suit them to existing conditions. And so we are back to the question: Do animals possess intelligence?

We can answer this by posing another question: Just what is meant here by 'intelligence'? There is nothing in such animal behavior which manifests true signs of *intellect* and *reason*, if that is what is meant by 'intelligence,' because there is no need to postulate the power of *abstract thinking* and the mental process of reasoning for the performance of their actions. If we examine the behavior of animals carefully, we notice nothing more than the *concrete connecting of concrete acts to concrete ends*. Perceptual insight and memory suffice to explain their behavior. Everything takes place on a *sensory* level.

If, however, we mean by 'intelligence' the 'capacity to improve upon native tendency in the light of past experience,' as William McDougall³ does, then we can admit that animals possess 'intelligence.' The name is of little importance, and a name should be given to the animal's capacity for learning by experience. 'The term is used quite extensively in modern psychology, and so we may as well adopt it. In that case, however, we should draw a sharp line of distinction between human intellect and animal intelligence, the former being the power of abstract thinking and the latter the power of sensory insight based on experience.

Animals, therefore, perform *two 'distinct types of actions'*: actions which result from 'instinct,' instinctive actions, and actions which result from 'intelligence,'

experiential actions. Both types involve *a sensory appreciation or estimation of the concrete usefulness or harmfulness of a perceived object with reference to the animal's organism or to the species*. The origin-principle underlying both types is the *well-being* of the organism or the species, and all actions conspire toward the realization of this well-being as the means toward the end.

Moderns use the term 'intelligence' in diverse meanings. As applied to brute animals, 'intelligence' is nothing more than the general cognitive power of the animal, and this power is one of the factors present in instinctive behavior. 'Instinct' is a complex pattern involving several capacities, cognitive, appetitive, and motor. There is no real distinction between the cognitive power manifested in the stereotyped instinctive behavior and the 'intelligence' as a general cognitive power capable of spontaneous learning; it is the same power which is active in every type of cognition. In both types of action, instinctive and experiential, the animal organism is stimulated to action by the perception of an object or situation presented by the central sense as something useful or harmful for its well-being.

St. Thomas Aquinas calls this cognitive power the *vis aestimativa* (the estimative power). In as much as man perceives the useful or harmful character of particular things not merely in a purely sensory fashion, but also by means of a collation of ideas, he calls this sense in man the *vis cogitativa* (the *cogitative power*) or *particular reason*, thereby distinguishing it from intellectual reason. D. Card. Mercier calls it 'the sense of wellbeing' (*le sens du bien-*

être). T. V. Moore combines the estimative power with the 'common sense' into what he calls the 'synthetic sense.'

Human Instincts

Man, too, is an animal organism. As such he has instincts and acts according to their impulses. Instincts are noticeable particularly in infants and children, because they live more on a sensory level. The adult's actions are so influenced by intellect and will, that he is seldom aware of the force the instincts exert on his conduct. On the other hand, some instincts never come into play until man enters into adolescence and adulthood.

If we attempt a *classification* of the instincts, we discover two fundamental divisions: those which serve the well-being of the *individual* and those which serve the well-being of the *species*. The preservation of the individual and the propagation of the species are the two great purposes which determine instinctive actions. No enumeration of the single instincts is altogether satisfactory, because it is difficult to isolate them out of the mass of intermingling activities.

Instincts of *self-preservation*. Most fundamental is the *food-seeking* instinct. Infants instinctively seek their mother's breast and know, prior to learning by experience, how to extract the milk through the complicated motor mechanism of sucking and swallowing. The food-seeking instinct perseveres through life; man must always seek food to sustain life. Akin to this instinct, but really its reverse, is the natural *aversion* man experiences toward many

substances which might be taken for food but are obnoxious to his well-being. Man also has the instinct of *curiosity*, the insatiable drive to investigate objects and learn what they are; he thereby discovers what objects are useful or harmful for his well-being. Then there is the instinct of *appeal*, expressed by sobbing, weeping, and whining, seeking aid and comfort in personal distress which cannot be relieved by personal effort. Man also has the instinct of *acquiring* and keeping or *hoarding* things, from toys to junk to homes and earthly wealth. The *constructive* instinct is strongly active in children, manifesting itself in games, play-acting, etc. Man also possesses the important communal instinct, the impulse to associate with others and form social groups; this instinct is the foundation of human society and government. In connection with the communal instinct we notice the instinct of *self-assertion*, which seeks to dominate the group, and the instinct of *submission* to the recognized superiority of others. In the face of threatening danger the instincts of *escape* or *combat* are unmistakably present.

Instincts of *race-preservation*. These instincts are too well-known to require more than cursory mention, for we observe them displayed at every turn. The *mating* instinct begins to manifest itself around the age of puberty. From that time on youth becomes sex conscious. Courting and the choice of a mate follow. If the union of husband and wife issues in offspring, the *parental* instinct induces the parent to give utmost care and protection to the children, even at the sacrifice of many personal comforts. There is, without

doubt, no nobler instinct in all nature than the self-immolation of parental love, because it is the most unselfish.

This enumeration of the human instincts, given for the sake of convenience, follows the well-known thirteen instincts given by William McDougall. William James enumerates a larger number; J. Lindworsky accepts but a single instinct (the striving after pleasure and happiness); others give other lists. The list mentioned in our text may not be complete or entirely accurate, but it should serve the purpose of enabling us to understand and appreciate human conduct better.

Nature of Instinct

Following the lines of certain philosophical systems, there are a number of *theories* which must be considered as an attempt to explain the nature of instinct.

Pure Mechanism

René Descartes (1596—1650) defended the purely mechanical concept of an organic body. The essence of every body is extension. To him, every organic body, including that of man, was no more than a machine. “I suppose that the body,” he wrote, “is merely a statue or earthen machine made by God on purpose to resemble us as much as possible.” Speaking of the functions of vegetancy and sentiency, “I want you, I say, to consider that these functions quite naturally follow in this machine from the mere arrangement of the organs, neither more nor less

than the movements of a clock or other automaton, from its weights and works."⁴

Like all other vital functions, the instinctive actions of animals, according to Descartes, are the mechanical actions of a robot, without psychical content. This theory represents mechanism pure and simple, with no place in the system even for a nervous reflex action. Today, extreme mechanism is rejected by all serious thinkers.

The Theory of Tropism

By 'tropism' biologists understand the involuntary movement of an organism or any of its parts, involving turning or curvature and axial orientation, and induced either automatically or in response to one or more stimulating influences. Such influences may be light, heat, electricity, a chemical substance, etc. Plants in a cellar, for example, send shoots toward the direction of the incoming light; seed shoots turn upward, while the roots turn downward, no matter how the seed may be placed in the soil; the amoeba, the *paramoecium*, the earthworm, and, in fact, most animals with a primitive nervous system are subject to tropisms of various kinds. When the organism moves in a direction toward the stimulus, the tropism is 'positive'; when in a direction away from the stimulus, the tropism is 'negative.' The influencing agencies being some form of physical or chemical energy, tropisms are conceived by biologists to be purely physical or chemical reactions, excluding all sensation and consciousness; hence, sensory cognition and appetency play no part in tropisms.

A few biologists and psychologists, among them A. Bethe (1898) and Jacques Loeb (1912), have attempted to explain all vital activity, including 'instinctive' action, in terms of *tropism*. The theory has not met with much success; it is doubtful whether any biologist of note today subscribes to it.

That tropisms exist in the lower forms of animal life can be accepted without dispute. That, however, is a far cry from the assumption that all animal behavior, and especially the highly complex trains of action observed in the instinctive performances of insects, fishes, birds, and mammals, are the result of tropisms. H. Jennings⁵ and S. Holmes, who have made extensive studies of the life histories of protozoa, are convinced that the principle of tropism is inadequate as the total explanation of the actions of even such simple beings as amoebae and *paramoecia*. The tactics of these animalcules manifest real behavior, not tropism, because their actions show individuality and spontaneity, without any observable change having occurred in the environmental medium.

When we apply the theory to the higher animals, it breaks down completely. Only the most deep-seated prejudice of mechanistic materialism could prompt a scientist to consider tropisms as an explanation, for example, of the spawning journeys of the eel and the salmon, of the seasonal migrations of the various species of game fowl, of the nuptial flight of bees and ants, of the nest building of birds, of the courting and mating of animals, of the parental care of mammals for their offspring, and so on. These types of activity may be mysterious and difficult to

explain, but it certainly is erroneous to degrade them to the level of a tropistic mechanism. *Cognition* and *experiential adaptation to circumstances* are too evident to be denied, and these are *psychical* elements far removed from the mechanical character of tropisms.

The Theory of Reflex Action

The *behaviorists* and *reflexologists* contend that all human and animal activities eventuate either visibly in muscular movement or invisibly in glandular secretion as a reflex action in response to physical stimuli. Reflexes may be either unconditioned (unlearned) or conditioned (learned). According to this theory, there is no need to appeal to 'consciousness,' 'sensations,' 'perceptions,' 'intelligence,' 'purposive action,' 'experience,' 'innate propensity,' and similar unobservable and unpredictable factors as an explanation for so-called 'instinctive' actions; all one need assume is a chain of reflexes released through response to external stimuli, the only difference between a simple reflex, such as the pupillary reflex, and instinctive action being one of degree in complexity. 'Psychic factors' must be eliminated and 'reflexes' substituted as the ultimate explanation of all animal behavior, including the behavior usually described as 'instinctive.' As a matter of fact, there is no such thing as an 'instinct,' as something which is an innate drive or urge to perform actions which are conducive toward the welfare of the individual and the species. An 'instinct,' conceived in this manner, is a superfluous concept of psychology. The concept of 'reflexes'

is sufficient to account for all actions usually ascribed to 'instinct.' Such is the attitude and theory of the thorough-going behaviorist and reflexologist, e.g., J. B. Watson.

Unfortunately, however, like the theory of tropism, to which it bears a close resemblance, the reflex theory is an *over-simplified explanation* of the type of animal actions which are grouped together as 'instinctive.' That some of these actions, or portions of the entire train of actions, are reflex in character, is undoubtedly true; but the fallacy of the reflex theory of instinct consists in arguing from the truth of the part to the truth of the whole, from the truth of the particular to the truth of the universal, from 'some' to 'all.'

INSTINCTIVE ACTIONS INVOLVE MUCH MORE THAN REFLEXES, namely, *psychic factors*.

We know that reflexes are responses of the neuro-muscular mechanism to physical stimuli, and these responses, to be genuine reflexes, must be effected through a reflex arc *independent of a determining or modifying conscious process*. Whenever an action is determined or modified by an antecedent or concomitant conscious process or perception or appetency of any kind, it is no longer a 'reflex action' in the meaning of the term as universally accepted in psychology. A reflex action may, or may not, enter consciousness, but the entire action must be carried out on a purely neuro-muscular level without conscious control. Reflex action, we claim, is insufficient as an adequate explanation of instinctive action.

For one thing, the response of an organism to a stimulus (heat, light, pressure, etc.) in a reflex is *direct, automatic, stereotype*. Given the stimulus, the response must follow. Instinctive actions, however, follow a different course. Preparation for the care of the prospective offspring (building a nest, constructing a cell, etc.) occurs only when the offspring is on the way. Birds are uninfluenced by the sight of twigs, grasses, etc., until the necessity arises to construct a proper abode for the eggs that are to be laid. Mud wasps are not interested in caterpillars, spiders, or grasshoppers, until the time arrives for them to lay eggs. The stimuli are thus present, and the reflex actions should take place, if instinctive actions were nothing more than a chain of reflexes; since they do not take place, it is evident that instinctive actions are not mere reflexes.

Again, reflexes are responses to stimuli, while instinctive actions are responses to *objects* and *situations*. Most instinctive performances represent a complex series of many types of actions quite different from the reflex responses to a stimulus such as light, heat, touch, and so forth; they may cover considerable territory and consume considerable time, but they always form a unitary activity, a planned whole, and they always center around definite objects or situations. Watch a bird build a nest, a squirrel collect nuts, a dog chase a rabbit, a mud wasp sting a caterpillar, a bee construct a honey cell, a colony of ants wage war on a neighboring colony, a beaver cut down a sapling, a hawk swoop upon a hen — these and similar typically instinctive actions reveal the operations of a

number of senses in *concerted perceptual responses*, not merely reflexes in response to isolated individual stimuli.

Furthermore, notwithstanding the typical character of the instinctive action, there is a degree of *spontaneity, initiative, and adaptability* in the chains of actions as a whole which is altogether foreign to the concept of a reflex. No two robins, for example, build their nests of absolutely the same material on the same kind of branch in the same kind of tree with the same kind of routine. Yet the final result is peculiarly similar for the purpose in hand, showing that, whatever may be the robins' response to the individual twigs, straws, branches, etc., 'the nest as a whole' is the guiding principle of the series of actions, permitting considerable latitude in the details of construction, so long as the nest as a whole is built. Or, consider a cat stalking a bird among some shrubs. The cat slinks along the ground, stops, crouches, moves forward again, now faster and now slower, taking advantage of every point of concealment, closing in on the unsuspecting victim, and then makes its climactic lunge, sinking its claws into the body of the bird and devouring it. The technique of hunting is typically similar in all cases, but the details change according to locale and circumstances; the instinctive principle is the same, but the execution is adapted to the prevailing conditions. There is very little in common between this type of perceptual action and the stereotype, automatic character of a reflex.

Finally, typically instinctive actions, seemingly so fixed in routine as to resemble the directness and inflexibility of reflexes, are at times *modified* to meet artificially

introduced conditions at variance with the routine of the instinctive actions. One need but recall the amazing performance of the dauber wasp repairing the damage done to its mud cells by K. D. McDougall. The wasp recognized the incompleteness of the cells and promptly went about to set things right by deviating from the routine procedure of its work. Henri Fabre narrates how he interfered with the usual routine of the *sphex* by moving the grasshopper a short distance away from the rim of the excavated nest, while the *sphex* was exploring the interior. He repeated the experiment dozens of times, until he grew tired and desisted, convinced that the unintelligent behavior of the *sphex* would result in an endless repetition of the same performance. Fabre was not patient enough. The Peckhams, husband and wife, also made the experiment of Fabre, but with a totally different result. After many repetitions of the procedure, as in the experiment of Fabre, the *sphex* dragged her prey, without depositing it at the rim as it had done heretofore, directly into the nest and finished her job. This action of the *sphex* manifests a perceptual appreciation of the task to be accomplished and a corresponding modification of the routine procedure usual under the circumstances.

These few incidents of animal behavior are sufficient to show that animals are not mere 'reflex machines,' but are organisms which are actuated in their instinctive actions by impulses set in motion by sensory data synthesized into perceptual wholes.

The Theory of Innatism

While the inner constitutional elements of the animal organism, as expressed in instinctive action, will always remain very much of a mystery, we are now in a position to outline the *true nature of instinct*.

The facts presented demand that the animal, during the course of instinctive actions, have the ability to perceive the various objects and their concrete relations, the immediate task to be performed in connection with these objects, and the present actions required as the task unfolds step by step toward the attainment of the goal as the end-result of the action series. Besides this perceptive ability, the animal must have the *executive ability to begin*, to develop, and to complete the task before it. That they possess this executive ability is obvious from the actual performance of the task. However, neither the ability of perception nor the ability of execution would be of any value, if the animal did not have the *propensity* or inherent impulse to undertake and execute the task under the proper conjunction of the circumstances of time and place. Animals do not perform instinctive actions except in definite circumstances of time and place; but when these circumstances are present, they show that they are driven by an irresistible impulse to begin and to continue the act until the goal is reached.

The intrinsic factors of instinct are *inherited* and therefore *innate*; they are not learned, at least not fundamentally and ultimately, by experience. Many instinctive actions are done but once, have never been observed before in operation, are performed practically at

birth, and are always carried through with unhesitating dispatch and with unfailing accuracy. Animals simply never have the opportunity to learn the sequence of some of these actions by experience. Hence, these intrinsic factors must be innate and inherited.

Two causes seem to unite to produce instinctive action. Certain objects excite the animal's imagination into activity; they are the *objective* cause. Due to a natural disposition present in the animal, the images aroused in the imagination excite the appetency, impelling it to perform certain actions in connection with the object perceived; these images are the *subjective* cause. Instinct, then, would seem to consist in the native power of associating certain images, which has as its object the immediate actions necessary for the task before it. These actions are subservient to the well-being of the individual and of the species and as such are *naturally* and *inherently purposive*.

The Origin of Instinct

In as much as instincts are inherited and innate, and not the result of experiential learning on the part of the individual animal, the question is unavoidable: *What is the origin of instinct?* Instinct emerges from the past into the present; its origin, therefore, must lie in the past, not in the present. Observation and historical record demonstrate that the same kind of animal, everywhere and always, performs its instinctive actions according to a pattern typically the same for all. How, then, was the instinct acquired by the species?

The crux of the problem is this: Since purposive action is the realization of a goal set in the future, with the selection of proper means to attain the goal, it definitely implies the *prevision of the goal and the means* required to attain the goal. Since instinctive actions are purposive, tending to realize the well-being of the individual and the species as a goal set in the future, instinctive actions should also require the prevision of this goal and the selection of its means of attainment. Such a prevision, though, apparently demands *intellectual foresight*. Someone, then, had to set the goal and determine the means for all the instinctive actions of the entire animal kingdom from the very beginning of animal life, provided these instincts have operated in the same fashion throughout the past eras of animal history. If these instincts did not operate in the same fashion throughout the past, but *originated in the course of time*, then how did they originate? They must be accounted for.

The Theory of Direct Creation

The defenders of this theory claim that the Creator, the Supreme Intellect, created the animals, endowing their constitution with all powers necessary for the survival of the individuals and of the species. Since the animals themselves are devoid of intellect and cannot, therefore, set a goal and select the proper means to attain this goal (the well-being of the individuals and of the species), the Creator implanted in their nature the instincts necessary for their preservation. Only the Creator has control over the entire animal kingdom, so that He alone, in their very creation,

could give them these native endowments manifested in instinctive behavior. The prevision of the goal and of the means required to attain the goal resides in the Creator, not in the individual animal; the Creator imposed the law of instinct upon the animal's nature, and the animal carries out the law without knowledge of its intrinsic purposiveness. This theory obviates the preposterous necessity of ascribing a superhuman intellect to subhuman animals, and gives an adequate explanation for the existence of purposive instincts present in all the individuals and species of animals throughout time and space. Since the animals themselves cannot be the cause of the origin of their own instincts, being completely dominated by these instincts, the cause of the origin of their instincts must be referred to the intelligent cause of their very nature, namely, to the Creator.

According to this view, the instincts, complete and perfect, came into existence in the animal nature by virtue of direct creation. These native endowments, then, were handed down from generation to generation to the present time through heredity.

There are *three particularly strong points* in favor of the theory of direct creation. It gives an adequate explanation of the exquisitely *purposive* character of instinct in all its manifestations, without the necessity of ascribing to the animal an intellectual insight into the purposiveness itself; it gives an adequate account of the *uniformity* of instinct in all the individuals of a species; and it also gives an adequate account of the *universal distribution* of instinct in the animal kingdom with respect to time and space.

The Theory of Evolution

The theory of evolution appears in a *variety of forms*, chief among which are the following.

According to *Charles Darwin's* theory of evolution by *natural selection*, the offspring of organisms differ in minor variations from the parents; and if these variations give an individual an advantage over its fellows in the struggle for existence, then by a natural process, called 'natural selection,' those best adjusted to their environment will survive ('the survival of the fittest'), while the others will perish. These small fortuitous individual variations are transmitted by generation and preserved by heredity, and in this manner the gradual accumulation of such variations gives rise to new species. The instincts originated in like manner, beginning with isolated, casual acts and gradually developing in the course of long periods of time into complicated, marvelously 'purposive' sets of instinctive actions. All is, of course, the work of chance, operating through the blind mechanism of natural selection. Most evolutionistic biologists now relegate 'natural selection' to a minor position among the factors operating in evolution.

Herbert Spencer, though an evolutionist, rejected natural selection. According to his view, all actions which are now instinctive were performed in the past *consciously* and *intelligently* for the satisfaction of some need or for the attainment of a definite goal. In the course of time these actions, through constant repetition, became hereditary habits, so that instincts are, so to say, the result of a 'lapsed intelligence.'

Henri Bergson's concept of evolution is unique. All organisms have evolved through the agency of an original life force, an *élan vital*, present throughout nature. Mind in its evolution developed along two different lines, along the line of 'intelligence' and along the line of 'instinct.' Intelligence developed in increasing perfection among the vertebrates and mammals, reaching its peak in man, while instinct developed to its fullest extent in the insects.

Emergent evolution, advocated by *Lloyd Morgan* and many moderns, has as its basic idea the principle that nature is the product of evolution in such a manner that entirely new and unpredictable properties originate through synthesis and thereby form new and higher levels of reality. These new properties are not mere resultants obtained by addition or subtraction from among previously existing properties; rather, these new properties have no counterpart in the lower levels and simply emerge' with specific characters not discoverable in the former (lower) levels. It is thus that mind, and with it instinct also, originated.

In all these variations of evolutionary theory, *no intrinsic goal* is assumed to exist for the process of evolution. It is a blind process produced by blind forces; everything just happens to work out this way. Instinct is merely one of these evolutionary products.

IT IS OUR CONTENTION THAT EVOLUTION, CONCEIVED IN THIS fashion, *cannot account for the origin of instinct.*

First, these evolutionary theories are based on the idea of the transmission of properties by generation through heredity. Now, very many instincts are of such a nature that the very existence of the individual and the generation of its offspring depend on the instinct being *perfect*, both as to ability and execution, *from the start*. Such are the food-seeking and mating instincts. Imperfection here would doom the individual and the species to extinction, because no second generation could arise to which anything could be transmitted. Unless, therefore, the first animal of a species were natively endowed with the complete instinct, there would be no future generations in which this instinct could 'evolve.' That being so, how did the instinct originate in this first individual? Certainly not through evolution.

Second, we must bear in mind that certain animals exercise a certain instinct *only once in their life*. The nuptial flight of the queen bee occurs only once. The cabbage butterfly lays its eggs only once and puts them under a cabbage leaf, never seeing its offspring. This larva becomes a butterfly, lays eggs in the beginning of summer on the leaves of a tree (contrary to the action of its parent); these larvae spin a cocoon for themselves on a tree, become butterflies in August, and then they spin their cocoon around the entire leaf with stem and twig, so that the eggs are properly protected for the winter. Thus the butterflies of spring act in an entirely different manner from those of autumn, and this only once in their life. Since they do not see their offspring, they cannot know the purposiveness of their action; but the purposiveness is there. It cannot be a question of hereditary habits or of a gradually acquired

variation or insight, because the butterflies perform the action but once and never know its result. And yet, if the action were not perfect from the start, there would be no second generation.

There are many such instances of instincts. How is it possible for the parent to acquire such an instinct and transmit it to the young, since they have never seen it exercised and have not themselves exercised it before? The parent certainly cannot transmit the instinct to the young present in the eggs, because these young exist already, and the parent first begins to exercise its care for the eggs after the young exist; and not to subsequent young, because it lays eggs only once. The parent does not even know that there is such a thing as an offspring. Yet the omission of a single step in this instinctive operation would be fatal to the offspring.

Third, the *care of the young*, as manifested in many instinctive actions, could never have been learned by the parent nor could it have been the chance result of blind forces of nature. The mud wasp, for example, paralyzes spiders, grasshoppers, and caterpillars by puncturing their motor centers with its stinger. It puts the paralyzed insect in the mud nest, pastes an egg onto the insect's body, and seals the nest, never to return to observe the results. The wasp itself does not eat flesh meat, but its young cannot exist on anything else in the beginning. If the insect were not paralyzed, the egg would be crushed through the squirming of the insect against the walls of the mud nest. But how should the wasp know this, since it never sees the results of its operation? And how should it know that its

offspring needs flesh meat? And how should it know that stinging the insect will stop its movements through paralysis? And how should it know where to sting and how many times to sting? If the very first wasp did not succeed in its amazingly purposive chain of actions, the species would not have survived the first generation. Experience could not have taught the wasp how to proceed, because it knows nothing of the result of its actions; insight is out of the question, for the same reason; a fortunate chance action could never be transmitted through heredity. Hence, again, if this entire set of actions would not be perfect from the start, the species would have become extinct with the first wasp. This example is just one among thousands.

Last, it is difficult to understand, on the principles of these evolutionary theories, how certain animals can transmit through heredity *an instinct they do not possess*, and how certain instincts can survive when their *possessors do not propagate their kind*. We refer to *neuter* insects, such as working bees, etc. "Neuter insects which do nothing to propagate their race can do nothing to transmit instinct or anything else. Yet these neuters do all the work of the community and require the most complicated instincts to do it. To fit them for their object, even their bodily form has often to be entirely different from that of the males and females; and in some species the neuters destined for different branches of work differ entirely from one another. Thus in one kind of ant there are working neuters and soldier neuters, with jaws and instincts extraordinarily different. Yet these neuters are the offspring

of males and females, none of whom, and none of whose ancestors, ever did a stroke of work in their lives.”⁶

No matter what type of the above-mentioned evolutionary theories one may choose to accept, their explanation of the origin of instinct leads to the almost inevitable conclusion that *the effect is greater than the cause*. While the instinctive actions are eminently purposive and intelligent in themselves, neither the animals nor the forces of evolution possess the requisite intelligence to give an adequate account of the rise, development, and survival of the instincts. Evolutionists usually appeal to the unknown ‘conditions of the past’ to gloss over any difficulties they may encounter in their explanation; but such an argument is a plain *appeal to ignorance* which explains nothing at all. So long as there is no intelligence working in or through nature, no adequate explanation for the intelligence manifested by the instincts will ever be forthcoming.

The Theory of Purposive Evolution

Do the arguments just adduced prove that evolution never took place? Not necessarily. Evolution itself, obviously, is not impossible, but it must be a *purposive evolution*. Since, however, purposiveness implies an intelligent foresight into the future, and since this intelligent foresight cannot be ascribed either to the forces of nature or to the animals themselves, the only possible alternative is the assumption that the *Supreme Intelligence endowed nature with a purpose* and with the necessary principles of action to realize this purpose *through evolution*. The required

intelligence would reside not in nature itself but in the Author of nature. It would then make little difference whether evolution were gradual or emergent in character. Animal species would arise, and their instincts with them, whenever the laws of evolution, imposed on nature by the Creator, would produce the conditions necessary for their origin. Hence, if the instincts derived their origin through evolution, this evolution must have been a purposive evolution imposed on nature by the Creator. Such a type of evolution would indeed render an adequate account of the origin of instincts and is acceptable.

Our *answer*, then, to the question of the origin of instincts must be that the instincts originated either through direct creation or through purposive evolution. Whether evolution has actually occurred, is a problem all by itself; and with that we are not at present concerned.

WE HAVE NOW STUDIED THE EXTERNAL SENSES — THE somesthetic senses, taste, smell, hearing, and sight; and also the internal senses — the central sense, imagination, memory, and instinct. These are the *cognitive sensory powers* of man and, more or less, of all animals. Man is indeed an organism endowed with many wonderful powers. But one great fact stands out in bold relief: Man is an *integral organism* manifesting a marvelous unity of nature amid all the complexity of parts and powers.

Summary of Chapter X

The fourth internal sense is instinct. It occupies itself with the well-being of the organism.

1. *The Concept of instinct.* Instinct connotes an impulsive tendency toward actions which are conducive to the well-being of the individual or of the species. This impulse is a native endowment, present in the animal prior to any learning by experience. Instinct also implies a cognitive element.

2. *The Existence of instinct.* Their behavior shows conclusively that animals possess an innate impulse, antecedent to all individual experience, determining them to certain uniform, purposive actions, useful for the individual and the species.

We may define instinct as an innate disposition which determines the organism to perceive (to pay attention to) an object of a certain class, and to experience in its presence a certain emotional excitement and an impulse to action which find expression in a specific mode of behavior in relation to that object.

3. *Instinct and Experience.* Instinct is not a rigid and uncontrollable automatism, but an innate disposition which possesses a certain amount of plasticity and flexibility, capable of being modified and adapted to the requirements of existing circumstances.

4. *Experience and intelligence.* Besides acting by instinct, animals also learn through experience, seeking what is good for them and avoiding what is harmful. Both

types of action involve a sensory appreciation or estimation of the concrete usefulness or harmfulness of a perceived object with reference to the individual or to the species. The animal's capacity to improve upon native tendency in the light of past experiences is often called *intelligence*. This power to estimate what is a concrete good or evil for well-being St. Thomas calls the *estimative power*.

5. *Human instincts*. The instincts of self preservation include food-seeking, aversion, curiosity, appeal, acquisition and hoarding, the constructive instinct, the communal instinct, self-assertion, submission, escape, and combat. The instincts of *race-preservation* include mating and parental care.

6. *Nature of instinct*. There are a number of theories. Pure mechanism considers the body as a mere machine without psychical content. The *theory of tropism* explains all animal actions, including instinct, as tropisms. The theory is erroneous, because cognition and experiential adaptation to circumstances are too evident to be denied. *The theory of reflex actions* interprets all instinctive actions in terms of a chain of reflexes. The theory is erroneous, because all evidence points to the fact that animal actions are determined or modified by antecedent or concomitant conscious processes of perception and appetency. *The theory of innatism* holds that the true nature of instinct involves the *ability to perceive* objects and their concrete relations, the immediate task, and the actions required to perform the task. It also involves the executive ability to carry out the task and the *propensity* to execute the task imposed by instinct. These factors are inherited and *innate*,

not the result of experiential learning. The stimulating object is the 'objective' cause; the natural propensity to carry out the action is the 'subjective' cause; these actions are then naturally and inherently *purposive*.

7. *The Origin of Instinct.* There are a number of theories which attempt to explain the origin of instinct.

The Theory of Direct Creation. According to this theory, the instincts, complete and perfect, came into existence in the animal nature by virtue of a direct creation.

The Theory of Evolution. The theory appears in a variety of forms: Darwin's theory of evolution through natural selection, Spencer's theory of lapsed intelligence, Bergson's theory of a life force, and Morgan's theory of emergent evolution. These theories, as proposed, are inadequate. Many instincts must be perfect from the start. Many are exercised only once in the life of the individual. The instinct of parental care could not have been learned, nor could it be the chance result of blind forces of nature. No logical account can be given of neuter insects and their instincts. Considering the purposive and intelligent character of instinctive actions, the origin of instinct, according to these theories, would mean that the effect is greater than the cause.

The Theory of Purposive Evolution. If instincts originated through evolution, this must be a *purposive evolution*, in the sense that the Creator endowed nature with a purpose and with the necessary principles of action to realize this purpose through evolution.

Hence, instincts originated either through direct creation or through purposive evolution.

Chapter 11

SENSUOUS APPETENCY

THE EXTERNAL AND INTERNAL SENSES AND THEIR FUNCTIONS HAVE now passed in review. Physical objects act upon the external senses, and these senses, in conjunction with the brain, react with sensations. Bits of information concerning these objects are thus conveyed to the sentient subject, are arranged into perceptual wholes, and then referred back to the stimulating objects. Thereby the properties of these objects, and through these properties the objects themselves, become known in a concrete sensory manner. This mental process is perception, and by its means external objects receive a *cognitional existence within the sentient subject*.

Sense knowledge is one phase of the life of the brute and of man. There is another phase, and it is equally important: it is *sensuous appetency*. Through perception the object is brought into contact with the subject; through appetency the subject is brought into contact with the object.

Concept of Appetency

In a very general way, *appetency*, or appetite, is *the tendency of one thing toward another*. This is clear from the etymology of the term, for 'appetency' is a Latin derivative (*ad* and *petere*) meaning 'to strive for,' 'to seek for,' 'to tend toward,' something. This tendency of one thing toward another is different in different types of objects.

The appetency present in the animal organism is a *conscious* appetency. It is termed 'conscious,' because the animal is aware of the object for which it strives, and this conscious apprehension of the object is a deciding factor in its striving. A double influence is present in conscious appetency: the 'objective' influence of the object attracting the apprehending subject; and the 'subjective' influence of the apprehending subject responding to this attraction by inclining toward the object with a conscious act of striving.

The appetency of animals is the result of a *spontaneous inclination* following conscious apprehension. Conscious apprehension and spontaneous inclination are *psychic* factors which are essential to the concept of appetency in animals.

Depending upon whether the knowledge preceding appetition is sensuous or rational, the distinction is made between *sensuous* and *rational appetency*. The latter is exclusively a human characteristic; the former is common to brute and man. Rational appetency is called the 'will.' In the present discussion we are concerned solely with sensuous appetency; rational appetency will receive a separate consideration in a later chapter.

Whatever may be the type of appetency, that which moves it to action is the *good*, and the 'good' is what is

suitable in some manner for the striving subject. The *well-being* of the organism itself is the all- embracing goal of its appetitive activities, because nothing is so basically good and suitable for an individual as its own being, its own nature.

An animal strives for an object because it satisfies some need, some demand, some exigency, some natural aptitude; it helps the animal in some way, or completes it in some fashion, or gives it pleasure in some form, or actualizes some potentiality of its nature, or has the capacity to realize some end and purpose in it. In a word, the animal strives for something because it is 'suitable' and in so far 'good' for the organism.

The very fact, though, that animals strive for anything at all, makes it clear that they cannot have their *complete actuality* from the beginning. If they had all their entity, if they possessed all the reality they are capable of receiving, they would no longer tend toward, or strive for, anything. To strive for something means that there is still some potentiality in their being which needs and demands realization. And in so far as something is suitable for this fuller realization and actualization of the animal, it will be 'good' for it. What, in particular, is suitable to a being, will naturally depend upon what the animal needs and what some other being has to *offer* for the satisfaction of this need.

Now, all animals have a nature or essence peculiar to themselves as members of a species and as individuals. And each such nature has a very real and definite *purpose or end within itself* which it tends at all times to protect and to

bring to full completion and *perfection*. A thing is 'perfect' when it has everything that it is supposed to have according to the exigencies of its nature. Perfection may be taken absolutely or relatively. Absolute individual perfection is the complete and final actualization of a being in its totality; relative individual perfection is the actualization of a being at a particular stage of its development as demanded by it at this point. In either case it possesses at the moment as much reality as its nature demands. Not everything will suit every type of animal nature, and the same thing will not suit every animal in all the periods of its life. What is suitable for a lion, need not be suitable for man; and what is suitable in infancy, need not be suitable in adulthood.

Each animal nature — and this, of course, includes the nature of man, because man is an animal organism — thus possesses a *specific natural tendency* within itself for its well-being, and things will be 'good' for it in so far as they promote its well-being. Nothing, however, will suit the nature of a being more than the very *entity of this nature*; its entity is an 'intrinsic' good for it. Consequently, all natures or essences are good for the individuals which possess them, and for this reason animals always strive to preserve and protect their existence. On the other hand, any *other beings* which help to develop or actualize the animal's nature will be suitable and therefore good for them; they are an 'extrinsic' good for the animal, and the appetency of the animal is directed toward them as means toward an end.

Reversely, no animal seeks what is harmful to itself. The animal *avoids what is harmful* to its nature, because it is

unsuitable for the satisfaction of its needs. If something harmful confronts the animal, the animal either avoids it or fights it; it never consciously seeks it and strives for it.

Sensuous appetency, then, has *two phases*: the *positive* phase, in which it consciously and actively seeks to attain what is suitable to its being; and the *negative* phase, in which it consciously and actively seeks to avoid what is harmful to its being. In both phases, appetency becomes active after something is consciously *apprehended* as being concretely good or harmful for the animal's being.

From the above it should be clear that sensuous appetency in the brute is closely linked to the *estimative power*. The estimative power enables the brute to recognize what is useful or harmful, good or evil, for its well-being. This knowledge may be acquired through experience, as when a cat or dog learns that certain cooked foods are good or harmful; or it may be instinctive, as when the hen knows that the hawk flying overhead is an enemy and the ducklings know that water is not harmful. The appetency of the brute is, of course, more conspicuous in instinctive actions, because these actions are dynamical in character and represent definite drives and impulses. On the other hand, the appetency manifested in experiential actions are more spontaneous in character and show more clearly that sensuous appetency depends upon the conscious apprehension of objects and situations as useful or harmful. In either case, however, the animal first perceives something to be useful or harmful, and then its appetitive power becomes active, urging the animal to tend toward

what is apprehended as good and to avoid what is apprehended as evil.

There is no necessity to *prove the existence* of appetency in the animal's constitution. The fact is too obvious to be denied. The foregoing chapter can very well be taken as containing the evidence of the appetitive striving of animals. Even a superficial study of animal behavior should suffice to convince the observer that animals possess appetency based on sensuous knowledge.

We can, therefore, define sensuous appetency as *a power in virtue of which a sentient being tends toward a consciously apprehended sensuous good and away from a consciously apprehended sensuous evil.*

Kinds of Appetency

Scholastic philosophers distinguish between two kinds of sensuous appetency: the *concupiscible* and the *irascible*. D. Card. Mercier suggests the more modern terms of 'propensity to enjoy' (*propension la pousse*) and 'propensity to fight' (*propension la lutte*). Mercier's terms, at any rate, explain what the scholastics mean by the more formidable terms of 'concupiscible' and 'irascible' appetencies.

The *reason* for the division lies in the *object* which arouses the appetency. This object may be something which is good and useful simply as such, something enjoyable in itself; no difficulties beset the attainment and enjoyment of such a good, and the animal strives for it *directly*. Or, this object may be something harmful and

disagreeable in itself; here, too, no difficulties beset the avoidance of the evil, and the animal avoids it by merely leaving it alone. An example or two will illustrate the point. A dog finds a bone and enjoys the appetizing morsel as he gnaws it to pieces; on seeing a boy approach whom he has learned to mistrust, he takes the bone between his teeth and leisurely trots off to a more secluded spot to finish his meal. A cat feels the warmth of the stove and curls up comfortably at its side, but it sedulously avoids coming too close, because on a former occasion it touched the stove and was burned. In these cases the attainment of the good and the avoidance of the evil were achieved directly and without any difficulty. Matters, however, are not always so simple. Sometimes obstacles stand in the way of obtaining or keeping a good and of avoiding or removing an evil. Then the animal must fight, and the direct object of appetency is the *removal of the obstacle*. If Fido, the dog, has a bone, and Spitz, another dog, sees this, a fight ensues: Fido fights to retain possession of the bone, and Spitz fights to obtain possession of it, and both fight to remove an obstacle which threatens to hinder them from enjoying the good they seek. A boy with a stick chases a cat, and the cat runs into a shed to escape its pursuer; but when cornered in the shed, the cat turns and fights furiously with naked claws in an attempt to drive its tormentor away. The life history of practically every species of animal will show similar types of behavior, disclosing these two fundamental tendencies.

The concupiscible appetency, therefore, strives directly for what is sensuously pleasant and useful and shuns directly what is sensuously unpleasant and harmful; the

object acts directly on the appetency as agreeable or repugnant in *itself*. The irascible appetency strives to obtain and retain an *arduous good* and seeks to avoid or remove an *arduous evil*; the object presents considerable difficulties and dangers which hinder the animal from obtaining and retaining what is a good or from avoiding and removing what is an evil, and these difficulties and dangers the animal seeks to overcome. It is thus seen that the concupiscible appetency is a more 'receptive' disposition, while the irascible appetency is a more 'active' disposition. The former is grounded on simple concupiscence, the latter on anger.

Aristotelian-scholastic philosophers differ in their opinion as to the *nature of the distinction* between concupiscible and irascible appetency. St. Thomas¹ and many others defend the view that a real distinction exists between the two, so that they are two different powers. Suarez² and others reject this view and claim that it is a single appetency expressing itself in two tendencies; the distinction is a *virtual* one, the foundation for the distinction being the two kinds of tendencies.

Feelings

Feelings and *emotions* are important factors in behavior. Feelings and emotions are mental reactions associated with cognitive and appetitive activity, and are usually grouped together under the common term *affective states*. Feelings are relatively simple states, while emotions are considerably complex in character.

Feelings and emotions are conscious *subjective* states and they differ according to the attitude of the experiencing subject. I look out of the window, let us say, and notice that it is raining. That is an act of knowledge, not a feeling. If I had intended to go on an outing, and the outing must now be called off, I experience displeasure; that is a feeling. Or, if I had intended to sprinkle the lawn and now am relieved of the chore, I experience pleasure; that is a feeling. The same fact and observation, therefore, is accompanied by different feelings, depending on the subjective condition of the observer.

In ordinary conversations the terms 'feeling' and 'emotion' have a rather vague and confused meaning. Psychologists, however, attach a specific meaning to these terms. 'Feelings,' to them, mean the more *elementary* affective states which are ultimate in character and cannot be analyzed or resolved into anything simpler as component states.

All psychologists agree that *pleasantness* and *unpleasantness* are elementary feelings. Formerly, it was customary to speak of 'pleasure' and 'pain.' At present, however, the term 'pain' is restricted to the sensation resulting from the stimulation of the sensory receptors for pain; in its stead they use the term 'unpleasure' or 'displeasure.'

Pleasant and unpleasant feelings may accompany *every type of conscious activity*, all the way from the sensations of the somesthetic senses to the highest operations of intellect and will. Mild pressure is pleasant; excessive pressure, unpleasant. Moderate temperatures of warmth and cold are

pleasant; extreme warmth and cold, unpleasant. Visceral sensations, when the functions are normal, are pleasant; when abnormal, unpleasant. Equilibrium, reported by the static or vestibular sense, is pleasant; disturbances of equilibrium, unpleasant. Proper exercise of the muscles and proper disposition of the bodily members produce kinesthetic sensations which are pleasant; otherwise, unpleasant. Many tastes and odors are pleasant; and many are unpleasant. Some color combinations impress us as pleasant; others, as unpleasant. Tones, harmonies, and melodies are pleasant; discordant noises are unpleasant. We find the same condition with respect to the operations of the internal senses. Depending upon the kinds of sensations presented to the central sense, the perceptions of objects and situations affect us pleasantly or unpleasantly. The recall of such objects and situations through imagination and memory affects us the same way; when we imagine or remember an act of kindness, we have a pleasant feeling, but if we imagine or remember a humiliating insult, we have an unpleasant feeling. Instinctive reactions to something agreeable are pleasant, while those referring to something disagreeable are unpleasant. The same is true of the strivings of sensuous appetency when not instinctive; seeking a sensuous good is pleasant, while fighting off a sensuous evil is unpleasant. Even intellectual and volitional processes are toned with pleasantness and unpleasantness. We experience pleasure, when we succeed in solving a difficult intellectual problem; we experience displeasure, when we are unable to solve it. Many decisions of the will are pleasant, especially when they follow our inclinations

and habits; when in opposition to these, they are decidedly unpleasant.

Pleasant and unpleasant feelings are thus seen to accompany all types of activity.

Kinds of Feelings

The question of how many kinds of elementary feelings there are, is a controversial issue. Many psychologists hold the view that pleasure and unpleasure (pleasant and unpleasant reactions) are the only genuinely elementary feelings. Others are not so sure. Those who maintain a larger number are not in agreement as to the number.

W. Wundt proposed an interesting *tridimensional theory* of simple feelings. There are, he says, three distinct pairs of feelings. The first pair are pleasantness and unpleasantness; some tastes are pleasant, others unpleasant. The second pair are excitement and restfulness (depression); the sensation of seeing a red color, Wundt says, causes excitement, while the sensation of seeing a blue color causes restfulness. The third pair are tension and relief (relaxation); waiting for the striking of a clock causes tension, and then the actual striking causes relief or relaxation from the tension. Wundt conceived these three classes of feeling to be like the three dimensions of space, so that any feeling could be accurately analyzed by placing it somewhere in these dimensions. Some feelings would be described as pleasant, exciting, and tense; some as pleasant, restful, and tense; others as unpleasant, exciting, and tense; others as unpleasant, depressed, and relaxed;

and so forth. Consider the following action in the closing seconds of a football game. The score is six to six, one team having just made a touchdown. The try for the point after touchdown is under way. The ball is snapped, placed, booted. The ball is in the air. This is the critical moment. One half of the crowd is pleasantly affected; the other half is unpleasantly affected. Everybody is tense, excited. It is good! The score is seven to six. The tension is over; relief takes its place. There are shouts of joy and moans of displeasure, surging excitement and numb depression. This incident is an illustration of Wundt's theory.

It is questionable whether excitement and restfulness, tension and relief are elementary feelings. Most psychologists are doubtful. T. V. Moore³ inclines to the view that these six feelings mentioned by Wundt are elementary. He thinks that there may be more, perhaps even as many elementary feelings as the number of emotions, each emotion being built upon the basis of a particular elementary feeling. Other authors suggest various feelings as possibly elementary, but there is no uniformity of opinion on the subject. All agree, however, that pleasant and unpleasant feelings are really elementary.

Pleasant and unpleasant feelings can be divided into *sensory* and *rational*. Aristotle⁴ calls attention to the fact that things and activities differing in kind are completed by things differing in kind. The activities of thought differ in kind from the activities of sense, and so, therefore, also do the pleasures which are their complement. The same line of reasoning applies to unpleasant feelings. His conclusion is sound. They are fundamentally different, as anyone will

recognize who compares the pleasant feeling attending the smell of a fragrant rose with that attending the acquisition of scientific knowledge, or who compares the unpleasant feeling of a gnawing hunger with that of one's failure to master a dominant habit. Because sensory and rational processes are of an entirely different order, the feelings of pleasure and unpleasure accompanying them must also be of a different order.

Aristotle⁵ also points out another division. Feelings of pleasure and unpleasure differ according to the *animal species*. Since each species has its proper function and nature, it will also have its proper pleasure and unpleasure. Horse, dog, and man differ in their pleasures, and Aristotle quotes the saying of Heraclitus that 'asses would prefer sweepings to gold.' Species differing in kind, therefore, also have pleasures differing in kind.

The Nature of Feeling

The question of the *nature of feeling* is also a controversial issue. Many opinions have been voiced on the subject.

Plato was of the opinion that pleasure is replenishment, the satisfaction of a want or need, just as pain or unpleasure is the lack of something which the being requires or needs.

Pleasure, then, is a *transition from pain*. Spinoza and Kant held similar views. Aristotle⁶ has already refuted this contention. Not all pleasures are satisfactions of organic cravings like hunger and thirst. Some pleasures do not follow pain or unpleasure. Aristotle mentions the pleasures

of smell, sound, and sight, the pleasures of learning, the pleasures of memories and hopes; these do not presuppose the lack of anything, as if these pleasures would supply an organic deficiency of some sort.

Pleasure, according to Descartes and Leibnitz, is the *consciousness of possessed perfection*. There is some truth in this contention; the consciousness of perfection possessed does give pleasure. There are, however, many kinds of pleasure of which this is not true. The consciousness of perfection and its possession, for instance, does not enter into such pleasures as are experienced in odors, sounds, and color combinations.

Passing on to the era of *modern psychology*, we encounter a variety of views.

Materialists and sensationalists identify feelings with *sensations*. Feelings and sensations, however, are not identical. First, when sensations are placed in the focus of attention, they become more vivid and can readily be observed and studied; but feelings become diffuse and, so to speak, evaporate when we pay close attention to them and seek to analyze them. Second, sensations proceed from sense organs and are localized in them; there are no organs for pleasure and unpleasure. Third, the senses are activated by specific stimuli; the eye responds to light, the ear to sound, and so on. The feelings of pleasure and unpleasure, however, are experienced with the activation of any and all the senses. Fourth, sensations are the direct result of external stimuli and are referred to external objects; they have the character of a representation of objects. Feelings have no such representative, cognitive

character, but are rather the conscious reaction to such sensations. Lastly, the pleasure derived from intellectual pursuits, such as is experienced in the solution of a philosophical or mathematical problem, has no meaning when interpreted in terms of sensations.

The theory that feeling is an *attribute of sensation*, is favorably accepted by some psychologists. This view is also erroneous. It is true, of course, that pleasant and unpleasant feelings have intensity, quality, and duration, like sensations; it is wrong, however, to say on that account that they are nothing more than attributes of sensations. For one thing, if their theory were correct, then these feelings should cease when the sensations cease. However, pleasant or unpleasant feelings which have accompanied sensations may persist a long time after the sensations themselves have ceased to be present. Again, the attributes of sensation (intensity, quality, duration) correspond in general to the attributes of the stimuli. The attributes of feelings, however, are strongly subjective in their very nature and do not parallel the sensations. Finally, the feelings which accompany the rational processes are not based on sensation at all; hence, they cannot be attributes of sensation.

PERHAPS THE MOST SATISFACTORY THEORY IS THE ONE ADVANCED BY *Aristotle* and held by the majority of scholastic philosophers. St. Thomas Aquinas subscribed to the views of Aristotle on this question.

According to Aristotle, activities, whether sensory or rational, are pleasant in so far as these activities are normal and natural for the active subject. Pleasure is a concomitant quality of every vital function, the result of a free and normal release of vital energy. The proportionate exercise of every vital power is accompanied by an appropriate pleasure. The healthy function of the vegetative organs, muscular exercise, seeing, hearing, tasting, imagination, intellection, volition — all are productive of a certain measure of agreeable feeling.

“Since every sense,” says Aristotle, “is active in relation to its object, and a sense which is in good condition acts perfectly in relation to the most beautiful of its objects . . . , it follows that in the case of each sense the best activity is that of the best-conditioned organ in relation to the finest of its objects. And the activity will be the most complete and pleasant. For, while there is pleasure in respect of any sense, and in respect of thought and contemplation no less, the most complete is pleasantest, and that of a well-conditioned organ in relation to the worthiest of its objects is the most complete; and the pleasure completes the activity. But the pleasure does not complete it in the same way as the combination of object and sense, both good, just as health and the doctor are not in the same way the cause of a man’s being healthy. (That pleasure is produced in respect to each sense is plain; for we speak of sights and sounds as pleasant. It is also plain that it arises most of all when both the sense is at its best and it is active in reference to an object which corresponds; when both object and perceiver are of the best there will always be pleasure,

since the requisite agent and patient are both present.) Pleasure completes the activity not as the corresponding permanent state does, by its immanence, but as an end which supervenes as the bloom of youth does on those in the flower of their age. So long, then, as both the intelligible or sensible object and the discriminating or contemplative faculty are as they should be, the pleasure will be involved in the activity; for when both the passive and the active factor are unchanged and are related to each other in the same way, the same result naturally follows."⁷

These acute observations of Aristotle furnish a neat explanation of the diversified character of pleasure, of its essential subjectivity, and of its spread over the entire mental field from sensory cognition and appetite to intellection and volition; for pleasure is the complement of every type of normal and healthy activity.

Aristotle's theory also explains the nature of *unpleasure* or *displeasure*. Displeasure is the result of an excess or defect in the activity of a power or faculty. There is a minimum and a maximum limit to the exercise of every vital power; to exercise a power below the minimum or beyond the maximum will be disproportionate and therefore disagreeable or even painful. For the same reason continuous pleasure is impossible; the power being limited, its activity is also limited, and so is the pleasure which accompanies it. When the limit is exceeded, the activity is no longer pleasant; it begins to dull and finally turns to displeasure. Change is necessary.

Emotion

Emotions, like feelings, are affective mental states; but unlike feelings, which are simple and elementary, emotions are a complex of constitutive factors. In emotions the individual is deeply stirred, agitated, excited, both in mind and body.

Elements both of *cognition* and *appetency* are dominant factors in emotion; in fact, they are essential to the concept of emotion. The animal nature reacts consciously to the presence of some good or evil, recognizes the good or evil present, and the entire organism grows excited and agitated in its effort to possess the good or avoid the evil. Consider the behavior of an affectionate dog greeting his master upon the latter's return after an absence of a few days. The dog grows tense with excitement, barks joyously, wags his tail, jumps up and down, frisks about, and in every way displays delight on again seeing his friend. And then consider the dog's behavior when another dog attempts to steal his bone. Every muscle is tensed with the readiness to fight, he crouches for the spring, snarls, bares his teeth, barks furiously, lunges at his enemy, bites viciously; he exhibits anger in his entire attitude and in every movement. These are instances of emotion, showing how the elements of conscious cognition and appetency are blended together into a complex affective state involving both mind and body.

Emotion always begins with the *perception* of some object or situation as an alluring good or a threatening evil. Perception is followed by an act of *appetency*, due to the aroused impulse to seek the apprehended good or avoid the

apprehended evil. *Changes* in bodily function then result leading to *behavioral reactions*. In this sequence, perception or cognition is the cause of the emotion, the behavioral reactions are the effect of the emotion, while the act of appetency, together with the concomitant bodily changes, form the agitated experience of emotion itself. This agitated experience, consisting of the appetitive act and the bodily changes, is the *very essence of emotion*; there can be no emotion without either the appetitive impulse or the agitated bodily condition. It should be borne in mind, however, that the cognitive, appetitive, and organic factors are irrevocably linked together in the integral emotional pattern.

That emotions can and do occur on a purely *sensory* plane, is evident from the facts that *brute animals* exhibit many types of emotional behavior. They show joy, fear, anger, lust, courage, aversion, and so on. In this respect brute and man are alike. Man, however, being also rational, frequently displays emotional behavior which is touched off by *intellectual* apprehension and *volitional* appetency. Entire nations can be aroused to intense emotion through the enthusiastic support of an ideal, such as the defense of their liberty. An individual may rise up in anger when a derisive epithet is spoken to him or when his honesty is questioned; he may be filled with exaltation when hearing a stirring piece of oratory or when contemplating a beautiful work or art. The cry 'God wills it!' sent hundreds of thousands of crusaders off to a long and bitter religious war. No matter what the particular cause happens to be, the emotional pattern is always more or less alike.

Bodily resonances are the *expression* of emotion. By 'bodily resonances' we understand the organic, physiological changes which occur in the body as a part of the emotional experience. Extensive experimental studies of these changes have been made, some of which are worthy of note.

The *face* of man has always been recognized as an index of emotion. The emotions play upon the facial muscles as upon an instrument. These muscles are very numerous and mobile, and the changes in emotion are reflected in the changes of facial expression, *Cardiovascular* changes, due to emotional excitement, also occur. These changes manifest themselves in the rise or fall of the blood pressure and in the rate and frequency of the heartbeat. Variations of this type are observed and measured.

Respiration also undergoes changes during emotion. There may be a decrease or increase in the frequency of breathing, or the breathing may become deeper or shallower. These variations are measured by the pneumograph.

In general, it may be stated, that in pleasant emotions the pulse is strengthened and retarded, and the breathing accelerated, while in unpleasant emotions the pulse is weakened and accelerated, and the breathing retarded.

Visceral changes also occur through the excitement of the emotional state. No matter what the type of emotion may be, if the excitement is intense, the adrenal glands pour out more of their secretion of adrenalin into the blood stream. This adrenalin in turn produces an increase of blood sugar. Adrenalin stimulates muscular contraction.

Increased muscular contraction consumes energy, and bodily energy is supplied by blood sugar. The purpose of this metabolic mechanism is apparent. Intense emotional excitement occurs when the animal faces a difficult situation which can be overcome only through a struggle involving considerable muscular exertion. If the animal is not to succumb to fatigue, muscular efficiency must be sustained, and it is sustained by the quick production of sugar through the action of the adrenalin.

If we now attempt a *definition* of emotion, we may describe emotion as an *affective mental state of the animal organism, following the cognition of an object or situation, characterized by strong feeling, by an impulse to action, and by physiological changes in bodily function.*

Kinds of Emotions

The *classification* of emotions is a difficult matter. The objects and situations occasioning them on the 'objective' side, the cognitive and appetitive factors, both sensory and rational, and the bodily resonances accompanying them on the 'subjective' side, are so manifold and variable in kind, quality, and degree, that it is extremely difficult to classify the emotions according to clear-cut types. Some attempts at a comprehensive classification will be enumerated.

The traditional *aristotelian-scholastic classification*, in vogue for centuries, is based on the *concupiscible* and *irascible* character of appetency. According to this classification, there are concupiscible and irascible emotions or, as these philosophers preferred to call them,

‘passions.’ Since the concupiscible appetency strives for the good and flees the evil, there are two fundamental emotions: (1) *love* of a good simply as such, and (2) *hatred* of an evil simply as such. This love and hatred may be referred to absent or present objects. We thus arrive at the corresponding emotions: (3) *desire* for an absent good, (4) *aversion* or abhorrence of an absent evil; (5) *joy* or delight in the possession of a present good, (6) *sadness* on account of a present evil. These six emotions refer to good and evil uncomplicated by a supervening difficulty. When the good is difficult to attain and the evil is difficult to avoid, the irascible appetency is aroused, giving rise to irascible emotions. From this standpoint, we arrive at five emotions: (7) *hope*, which considers the good as absent and difficult, but possible of attainment; (8) *despair*, which considers the good as absent and difficult and impossible of attainment; (9) *courage*, which sets itself against a threatening evil considered as conquerable; (10) *fear*, which considers the threatening evil as unavoidable; (11) *anger*, which is an emotion aroused in the presence of an evil that has actually befallen the organism. Anger has no opposite emotion. The present good calls forth the emotion of joy; the present evil, if it does not provoke anger, calls forth sadness; anger thus has no paired member.

It will be noticed, that the concupiscible and irascible emotions correspond to what modern psychologists often refer to as ‘normal situations’ and ‘emergency situations.’ There can be no question that this classification rests on a solid logical and psychological foundation. The objection is made that the classification is incomplete and rudimentary,

many emotions being omitted; no place is found in the list for emotions like pity, surprise, awe, regret, anxiety, and many others. Many emotions, it is true, are omitted. The list, however, contains only the *primary* and *fundamental* emotions; all others would be blends of some sort, and no classification can enumerate all these.

Maher⁸ gives a classification which is more in accord with the trends of modern schools of psychology. He classifies the emotions as follows: (1) *Self-regarding* emotions, which include self-esteem, self-complacency, self-commiseration, pride, vanity; remorse, self-condemnation, shame; fear, anger, sense of power. (2) *Altruistic* emotions, among them primarily sympathy; its opposite would be antipathy. (3) *Feelings* attached to intellectual activity, among which should be enumerated novelty, surprise, wonder. (4) *Aesthetic* emotions, which are aroused by a contemplation of the beautiful, the sublime, and the ludicrous. (5) *Moral* sentiments, which embrace feelings of obligation, responsibility, approbation, disapproval, remorse, self-commendation, reverential fear, guilt, and so on. With regard to this classification, Maher himself observes that the categories are not mutually exclusive. The question can also be raised whether all of these enumerated items contain the element of excitement and agitation universally associated with emotion; there need not be anything exciting, for example, about self-esteem or disapproval or the sense of responsibility, etc. Generally speaking, however, the classification is serviceable.

W. McDougall's⁹ classification meets with approval in many quarters. He bases his division on the instincts. First,

there are fourteen *primary* emotions, corresponding to the fourteen instincts which he enumerates (the instincts are enclosed in parentheses): fear (instinct of escape), anger (combat), disgust (repulsion), love or tenderness (parental), distress (appeal), lust (mating), curiosity or wonder (curiosity), subjection (submission), elation (assertion), loneliness (gregarious), gusto (food-seeking), feeling of possession (acquisition), feeling of creativeness (construction), and amusement (laughter). Second, there are the blended or *secondary* emotions. McDougall gives a number of instances of the blending of primary emotions, such as scorn (anger and disgust), awe (admiration and fear), gratitude (love and the sense of inferiority), and so forth. Third, *derived* emotions. Among these he enumerates confidence, hope, anxiety, despondency, despair, regret, remorse, sorrow, joy, surprise. While this classification is in many respects a good one, one must object to the fundamental point of division. It seems rather arbitrary to base the primary emotions on the instincts alone. What is 'primary' should be relatively simple and elementary in character; but some of these so-called 'primary' emotions are anything but simple and elementary. Joy and sorrow, for example, seem more simple and elementary than a sense of inferiority or a feeling of creativeness.

AN INTERESTING AND PROMISING ATTEMPT AT A *NATURAL classification* of the fundamental emotions has been made by G. I. Schramm,¹⁰ in view of the results obtained from experiments conducted in late years on animals and

children. Prominent in these researches were M. Bentley, K. M. Bridges, C. Bühler, W. B. Cannon, H. Carr, I. F. Dashiell, P. Furfey, A. Gesell, F. Goodenough, H. S. Jennings, W. Kno, C. P. Richter, G. I. Schramm, M. and I. C. Sherman, E. L. Thorndike, E. C. Tolman, L. S. Tsai, J. Watson, R. S. Woodworth, T. P. Young, and many others.

Schramm distinguishes *three main factors* as responsible for emotional behavior: the nature of the stimulus acting on the animal organism; the nature of the organism reacting to the stimulus; the conditions separating the organism from the stimulus. All three factors have an important bearing on the classification of the emotions, because they give rise to fundamental types of emotional states.

Stimuli, which arouse the emotions by acting on the organism, are objects or situations that affect the perceiving organism as something good or evil, agreeable or disagreeable, for its maintenance. Schramm terms this quality of a stimulus the factor of its 'favorableness' or 'unfavorableness.' For example, the sight of food is a favorable stimulus for an animal, while the sight of an enemy is an unfavorable stimulus.

Much depends, too, on the *nature of the organism*, namely, on its age, health, maturity, native and acquired bodily equipment, etc. In the presence of a favorable or unfavorable stimulus, the organism may have a constitution with marked superiority, or with marked inferiority, or with general competence (superiority-inferiority), making it very easy, or very difficult, or moderately easy (difficult) to obtain the good and avoid the evil. Anatomically, animals possess

distinct structures and powers which enable them to obtain a good and avoid an evil: senses for perceiving an object or situation at a distance (sight, hearing, etc.); bodily members designed for moving toward, or away from, an object (wings, legs, fins, etc.); structures for apprehending and holding an attractive good or fending off and destroying a threatening evil (claws, teeth, stings, etc.); receptors and functions of deep sensibility for intimate contact and possession (organs of nutrition, reproduction, etc.). Schramm groups all this under the factor of the 'superiority,' 'superiority-inferiority,' or 'inferiority' of the organism; for brevity's sake, he speaks simply of the factor of 'superiority.'

The factor of *separating conditions* comprises the elements of time, space, obstructions, etc., which intervene between the stimulating object or situation and the reacting organism. Such conditions obviously evoke different emotions. Depending on the anatomical sub-factors just mentioned, one must distinguish four critical loci or zones in the time and space extension of an emotional behavior period. These are: the point where the organism becomes aware of the stimulus ('point of distant fixation'); the point where the organism seeks to overcome the separating conditions or obstructions ('point of locomotion to obstruction'); the point where the organism makes external contact with the stimulus object by seizure or combat ('point of external contact'); the point where the organism makes intimate contact with, or takes possession of, the objects ('point of intimate fixation'). Schramm calls this

temporal period and situational area of emotional behavior the factor of 'space relation.'

It is on the *interplay of these three basic* factors that Schramm builds up his natural classification of emotional phases, as can be seen in the accompanying table.

A PERIODIC TABLE OF EMOTIONAL PHASES

FACTOR OF ORGANISM'S	FACTOR OF SPACE-RELATION				FACTOR OF STIMULUS'S
	<i>Point of Distant Fixation</i>	<i>Point of Locomotion to Obstruction</i>	<i>Point of External Contact</i>	<i>Point of Intimate Fixation</i>	
Superiority	Orientation Desire	Approach Hope	Success Dominance	Adjustment Elation	Favorableness
Superiority-Inferiority	Orientation Desire	Approach Hope	Success Submission	Adjustment Delight	Favorableness
Inferiority	Orientation Jealousy	Approach Despair	None None	None None	Favorableness
Superiority-Inferiority	Orientation Anxiety	Approach Fear	None None	None None	Unfavorableness
Inferiority	Orientation Repugnance	Approach Courage	Failure Inhibition	Adjustment Depression	Unfavorableness
Superiority	Orientation Repugnance	Approach Courage	Success Vengeance	Adjustment Disgust	Unfavorableness

EXPLANATION OF TABLE: "In the above table it will be seen that the superior organism reacts in an approaching or attacking manner, and the ensuing conflict with an obstruction or resistant stimulus object ends in a success for the organism. The activity of the partially superior organism ends in a partial victory, compromise or submission with dependent maintenance. The completely inferior organism neither surmounts the obstruction nor attains the desired stimulus object. It continues suspended in a vicious circle of desire and despair, or anxiety and fear. The favorable stimulus has an attracting influence in all its factorial situations and yields satisfaction when attained in whole or in part. The unfavorable objective has the opposite effect.

"Among the listed phases, the outer columns are mild reaction phases, since they are essentially fixation states.

The inner columns are of emergency behaviors and involve large muscle activities in overcoming obstructions and resisting stimuli objects. The three upper lines of phases yield satisfying experiences, the lower three are dissatisfying. The top and bottom lines of phases have dominance resemblances, the inner lines list the submissive behaviors, the innermost have no contacts with the stimuli nor permanent adjustments, they are deficiency reactions.”¹¹

Many other classifications have been attempted. None, however, seem entirely satisfactory.

The Nature of Emotion

Emotions are elusive reactions. Though powerful in their expressions when unrestrained and left to run their natural course, they subside rapidly when studied by the subject experiencing them.

Three decisive factors stand out prominently in all emotional reactions. First, emotional reactions follow the *perception* of some object or situation which is recognized as being good or evil for the percipient subject. Second, this perception is followed by an *impulse* to acquire the good or to avoid the evil. Third, there ensues the stage of *mental excitement* and the actual *release of energy* (bodily resonance) in the effort to acquire the good or to avoid the evil. Cognition (perception), appetency (conation), and organic agitation (bodily resonance) are inextricably bound together as factors in all emotional reactions; if one of the factors is missing, there is no genuine emotion.

Some authors incline to the view that emotions are the acts of a *third power* or faculty, radically distinct from the powers of cognition and appetency. It is unnecessary to postulate a third power of this sort. No sufficient evidence has ever been produced to show the existence of this third distinctive power or aptitude. An analysis of emotional states shows that they are nothing more than complex products of *appetency or conation* (striving) in the presence of a perceived good or evil affecting the well-being of the organism. Emotions are essentially a protective mechanism, insuring the well-being of the individual by arousing it to action in procuring what is good and in shunning what is harmful.

One must distinguish between *impulse* and *emotion*; they are often confused. An impulse is always a conscious tendency toward or away from something, a 'wanting to act,' and it need not be accompanied at all by any sort of excitement or agitation. I may, for example, want to eat a piece of candy or take a stroll; that is an impulse, and I may, or may not, carry out the impulse. Ordinarily speaking, however, I do not have a 'strong feeling' about the matter. But if someone were to snatch the piece of candy from my hand, just as I am about to put it into my mouth, I might resent this strongly and 'feel very angry' about it; that would be an emotion. One must, therefore, make a distinction between the 'agitated conscious state which is an emotion and the mere 'tendency to do something' which is an impulse.

It is also well to distinguish between *instinct* and *emotion*. Instincts are always native impulses of some kind

or other, and, since emotions are distinct from impulses, there must also be a distinction between emotions and instincts. Instincts involve actions directed toward external objects, while emotions are more in the nature of internal responses. Instincts are often active over a long period of time, while emotions are as a rule ephemeral in character. Emotion and instinct frequently go together, but not always. A person, for example, may follow the instinct of escape by keeping well away from the edge of a precipice without experiencing the mental agitation of fear on that account. Reversely, a person watching an angry lion in a cage may feel the emotion of fear, but the instinctive impulse to combat or escape may be absent because there is no danger. Again, we may experience the emotion of joy in watching the graceful flight of a bird or the playful gambol of a lamb; it would hardly be appropriate, however, to say that some instinct of ours toward the bird or the lamb were thereby called into action. On the other hand, there are also similarities between emotion and instinct. Both are complex patterns involving cognitive, appetitive, and motor factors; both seem to tug at the autonomic nervous system. Emotion has an essentially appetitive core; instinct, an essentially cognitive core.

There is also a distinction between *emotion* and *feeling*. Feelings are simple, emotions are complex. The feeling of pleasantness or unpleasantness often accompanies sensations directly, as in taste or smell. Sensations, as such, never arouse emotions. Objects and situations, to be capable of arousing emotions, must have a *meaningful* significance for the subject, must be recognized as

something beneficial or harmful; experience and knowledge, therefore, are prerequisite conditions for emotion. A slap in the face, for example, may be painful or disagreeable, no matter whether it be given in a playful or in a vindictive mood. My personal reaction, from an emotional standpoint, will be very different in the one case and in the other: If I realize that the action was playful, I may laugh at it; but if I realize that the action was intended as an insult, my resentment and anger may be very keen and intense, Why the different emotional reaction? The difference cannot lie in the slapping itself, because that action is a single action. It can lie only in the insight into the meaning of the action taken as a whole in the context of the entire situation. In man, at any rate, emotion has its source in intellectual thought.

In the *traditional* view, *bodily resonance* is the ‘effect’ of emotion. Because consciousness is in an excited, ‘stirred-up’ condition, it affects the body, giving rise to a number of physiological changes which are the expression of emotion. In other words, the emotions are the cause of bodily resonance as an effect. The sequence would then be as follows: the perception produces the emotion in the perceiving subject, and the emotion then produces the bodily changes; because a man feels fear, he trembles, and because he feels anger, he clenches his fist and strikes. The *James-Lange* theory of emotion reverses this sequence.

According to this theory, propounded by William James (1884)¹² and C. Lange (1885), the “bodily changes follow directly the perception of the exciting fact, and our feeling of the same changes as they occur *is* the emotion.” As James

puts it in his usual graphic style, "the more rational statement is that we feel sorry because we cry, angry because we strike, afraid because we tremble, and not that we cry, strike, or tremble, because we are sorry, angry, or fearful, as the case may be." According to this view, perceptions cause bodily resonance, and bodily resonance causes emotion.

James appeals to *three sets of facts* as proof of his theory. He shows that objects excite body changes, and every change of consciousness registers in the organism as in a sounding board. He points out that every bodily change is felt the moment it occurs. Finally, he appeals to the introspective fact that if we imagine a strong emotion and then abstract from this emotion all the feelings of bodily symptoms, there is nothing left of the emotion itself.

The theory is untenable. The facts he adduces are admitted. These facts, however, merely prove that *bodily changes are an integral part of emotional experience*. No one denies that. But his argument is beside the point. What James should prove is that the emotion is the effect, and not the cause, of bodily changes. He does not prove this point; he shows that bodily changes are always present in emotional reactions, but he does not show that these changes precede the emotional excitement.

If James' theory were correct, then *genuine emotions* should be aroused in a subject whenever the proper physiological conditions are present. Consider the following case. In thalamic lesion, hyperactivity in the thalamus follows, and as a result the patients often break out into spasms of uncontrollable laughing or crying. According to

the James-Lange theory, this laughing and crying should be true emotion. The patients themselves, however, confess only to a feeling of shame, because they feel ridiculous for laughing or crying without reason; they felt no gladness in their laughter and no grief in their tears, both laughter and crying occurring against their will and better judgment.

Again, if the James-Lange theory is correct, the recordings of the *plethysmograph* and the *pneumograph* made during experiments on emotional reactions, should precede the emotional state itself. The facts, however, are against the theory. These instruments register a perceptible interval of time between emotion and bodily change, the mental state always preceding the bodily symptoms. Practical application of this principle occurs in the so-called 'lie-detector' experiments, where the mental excitement of telling a lie in the face of damaging admissions is always followed by changes in pulse, respiration, etc., which subsequently show up on the graph. Bodily resonance, therefore, follows emotions as the effect follows the cause. This result is also observed in *hypnotic* experiments. Certain emotions, if suggested, produce bodily changes which, when recorded by the plethysmograph and pneumograph, follow the same sequence as in the case of real emotions: first the mental state, and then, after an interval, the bodily changes.

Furthermore, the work of W. Cannon on the *secretion of adrenalin* during emotional excitement does not favor the James-Lange theory. The perception of danger arouses the emotion of fear, but it takes some time before the secretion of adrenalin produces the physiological changes in the

organism; these changes occur too late to be the real cause of the emotion. When adrenalin is injected into the system of a person, this person feels the sensations of muscular tension, etc., usually experienced under the stress of emotion, but the emotion itself, as a strong affective state of consciousness, is not experienced on that account.

Finally, the visceral changes are *common to all emotional* states. The same bodily changes, for example, occur in deep anger and in deep fear. No reason can be assigned why, according to the principles of the James-Lange theory, the same bodily resonance should produce such radically different emotions. Since anger and fear are specifically distinct emotions, they should be caused by specifically distinct, not common, bodily changes. The cause, therefore, must lie elsewhere.

For these and other reasons, the James-Lange theory must be rejected as an inadequate explanation of the nature of emotion.

Walter B. Cannon¹³ has advanced what he terms the *thalamic* or *emergency* theory of the emotions. The thalamus, as we know, is a part of the brain stem. On the basis of experiments with animals, Cannon showed that animals will manifest all the bodily changes and expressions of emotion, even when the cortex is removed, provided the thalamus is left intact; but when the thalamus is severed from the rest of the central nervous system, the bodily resonances disappear. According to Cannon's conclusions, then, the stimuli for emotional reactions first travel to the thalamus. A double neural action now takes place. A part of the neural activity passes upward to the cortex, arousing

conscious emotional experience; a part passes downward into the motor channels controlling the viscera and the skeletal muscles, thereby producing the bodily changes so noticeable in emotional excitement. The cortex itself, in consequence of the conscious experience, may, and usually does, send nerve impulses back to the thalamus, reinforcing or inhibiting the neural impulses sent to the viscera and musculature. The thalamus, therefore, is a center of coordination for emotional behavior.

In general, the role of the thalamus in emotional responses seems pretty well established; but this role is a subordinate one in the whole context of emotional responses. It does not explain everything. Experience shows, for example, that anger, fear, and very many other emotions are aroused through conscious concentration on *imagined* or *remembered* objects and situations. Here no neural impulse passes through the thalamus in the first place; everything begins with images in the cortex, and from the cortex the neural impulses are probably sent to the thalamus. It will thus be seen that the thalamic theory does not give enough prominence to the *cognitive* element of emotion.

The findings of experimental psychology in the field of emotion bear out the explanation of *St. Thomas Aquinas*,^{[14](#)} in which he insists that emotion involves the psychic factors of cognition and appetition, and also the organic factor of bodily change. Cannon's experiments show that 'emotional expressions' may be present without true emotion; but true emotions, in a normal individual, always imply bodily

resonance as an integral part of emotional experience, something which Aquinas had recognized long ago.

IN LOOKING BACK OVER THE PRESENT DISCUSSION, WE ARE AGAIN struck by the fact that the conative processes of sensuous appetency, together with their accompanying feelings and emotions, are intimately linked with the cognitive processes of the various senses. All are subservient to the welfare of the animal as a whole. Sensuous appetency is another phase of man's mental life which highlights the fact that man is in all truth an integral organism.

Summary of Chapter XI

Sense knowledge is one phase of mental activity; sensuous appetency is another phase.

1. *Concept of Appetency.* In general, appetency is the tendency of one thing toward another. In animal nature it is conscious' appetency, the result of a spontaneous inclination following apprehension. That which moves the appetency to action is the good, the suitable. The animal organism thus seeks what is good or useful for itself and avoids what is evil or harmful for itself. Sensuous appetency is defined as *a power in virtue of which a sentient being tends toward a consciously apprehended sensuous good and away from a consciously apprehended sensuous evil.*

2. *Kinds of Appetency.* Sensuous appetency is either *concupiscible* or *irascible*. The former strives directly for what is good in itself; the latter strives to obtain and retain an arduous good and to avoid or remove an arduous evil. Some scholastic philosophers look upon the distinction between concupiscible and irascible appetency as a real distinction; others, as a virtual distinction.

3. *Feelings.* They are affective mental states and as such subjective in character. By feelings, as distinct from emotions, psychologists understand *elementary* feelings. All agree that *pleasant* and *unpleasant* feelings are elementary. They may accompany every type of conscious activity.

4. *Kinds of Feelings.* Many psychologists recognize only pleasantness and unpleasantness as elementary; others enumerate a larger number, but there is no uniformity of

opinion. Wundt proposed a *tridimensional* theory of simple feelings: pleasantness and unpleasantness; excitement and restfulness; tension and relief.

Pleasant and unpleasant feelings can be divided into 'sensory' and 'rational.' Aristotle contends that pleasure and displeasure differ in the different species of animals.

5. *The Nature of Feeling.* Plato thought that pleasure is the satisfaction of a want, a transition from pain. Descartes and Leibnitz thought that pleasure is the consciousness of possessed perfection. Materialists and sensationalists identify feeling with sensation. Others consider feeling to be an attribute of sensation. According to Aristotle and most scholastics, pleasure is a concomitant quality of every vital function, the result of a free and normal release of vital energy; displeasure is the result of an excess or defect in the activity of a power or faculty.

6. *Emotion.* Emotions begin with the *perception* of some object or situation as an alluring good or a threatening evil; perception is followed by an act of *appetency*, seeking the good and avoiding the evil; *bodily changes* then result, leading to behavioral reactions. Emotion is an affective mental state of the animal organism, characterized by strong feeling, by an impulse to action, and by physiological changes in bodily function.

7. *Kinds of Emotions.* The aristotelian-scholastic classification enumerates eleven primary emotions. There are six concupiscible emotions: love and hatred, desire and aversion, joy and sadness. There are five irascible emotions: hope and despair, courage and fear, and anger. Maher classifies them as follows: self-regarding emotions, altruistic

emotions, feelings attached to intellectual activity, esthetic emotions, and moral sentiments. McDougall divides emotions into 'primary,' based on the various instincts, 'blended' or 'secondary' emotions, and 'derived' emotions. G. J. Schramm classifies the fundamental emotions by distinguishing three main factors as responsible for emotional behavior: the nature of the stimulus acting on the organism; the nature of the reacting organism; and the conditions separating the organism from the stimulus.

8. *The Nature of Emotions.* Three factors are involved in emotions: perception; impulse; mental excitement and bodily resonance. No third power is necessary, in order to account for emotions; they are complex products of appetency or conation in the presence of a perceived good or evil affecting the well-being of the organism.

One must distinguish between emotion and impulse, emotion and instinct, emotion and feeling.

In the traditional view, bodily resonance is the effect of emotion. In the *James-Lange* theory, emotion is the effect of bodily resonance. The arguments of James are beside the point, because they merely show that bodily changes are an integral part of emotional experience, something no one denies. Many facts speak against the theory.

W.B. Cannon advanced the *thalamic or emergency theory* of emotion. The thalamus is the center of coordination for emotional behavior. The theory does not account for emotion arising from imagined or remembered objects and situations.

St. Thomas Aquinas explains emotion on the basis of the psychic factors of cognition and appetite and of the

organic factor of bodily change. Trends in modern psychology confirm his view.

Chapter 12

INTELLECTION

IN THE FOREGOING CHAPTERS WE CONSIDERED MAN ON THE sensory level of his being, treating those processes which he has in common with brute animals. These processes include sensory cognition, as acquired through the mediation of the various external and internal senses, and sensuous appetency. Though different types of function, they are interrelated and interdependent in many ways, so that they are activities of one and the same integral organism.

Intellectual and volitional activities were also mentioned now and then, but more or less incidentally. Due to the complexity of man's nature, intellection and volition frequently intermingle with sensory function, so that we do not find it easy to exclude them, even when endeavoring to give a description of sensory function as such. The reverse is also true; though we will now discuss the *rational processes* in man, it will not be possible to exclude the sensory processes completely, because the rational processes presuppose the sensory processes as an antecedent requisite condition.

The rational processes are characteristically human functions. These are *intellection*, or rational cognition, and *volition*, or rational appetite. Just as in the sensory field sensory cognition precedes sensuous appetite, so too in the rational field intellection precedes volition. We will, therefore, first discuss the function of intellection and then that of volition.

Intellection

Viewed from the standpoint of psychological experience, it is universally recognized that intellection comprises *three distinct processes*: the formation of ideas or concepts, the formation of judgments, and the formation of inferences.

The *concept or idea* is the intellectual representation of a thing. It is expressed in the definition of a thing. When we say that 'Man is a rational animal,' we give the definition of 'man,' and that is the concept or idea we have of 'man.' It is not the words of the definition that is of importance, but the meaning behind the words; it is what we 'have in mind' in the use of these words that expresses the concept or idea. The words will change from one language to another and even in the same language, but the meaning, and therefore also the concept or idea, is always the same. We could, for example, also define 'man' as 'a material, living, sentient, rational substance'; the words are different, but the idea is identical.

The *judgment* is the pronouncement of agreement or disagreement between two ideas. It is expressed in the declaratory sentence, as when we state that 'Oaks are

trees' and 'Birds are not mammals.' We have the concepts 'oaks,' 'tree,' 'birds,' and 'mammals,' and then express their agreement or disagreement among themselves as they appear to our mind. Here also it is not so much a question of the words used in the sentence as of the knowledge present in our mind.

An *inference* is the reasoning process in which, from truths known, we conclude to a truth previously unknown. Somebody asks: 'Fred weighs more than Jack, and Al weighs less than Jack; does Fred weigh more or less than Al?' We conclude that 'Fred weighs more than Al' and 'Al weighs less than Fred.' From the data given we drew our conclusion; that is an inference.

Concepts, judgments, and inferences are grouped under the heading of 'intellection,' and psychology is interested in the process of their formation. If we have a clear knowledge of this process, we can venture a conclusion as to the nature of intellection.

Attention and *abstraction* play an all-important role in the formation of concepts. They throw considerable light on the inner working of the mind in this connection, and it is imperative to understand their operation.

Attention

By attention we understand the direction of the cognitive process toward an object, an activity, or a thought. Attention brings something within the focus of conscious activity, so that the mind becomes aware of its presence. The object upon which we concentrate our attention may be

of the sensory order, as when we pay attention to the flight of a bird or the color of a flower, or it may be of the intellectual order, as when we pay attention to the products of our thinking processes.

Attention is analogous to vision. The objects which are focused upon the center of the retina are clear and distinct, while those whose image falls upon the peripheral portions of the retina are vague and diffused. At most, we are able to see only a few objects clearly at one time — about half a dozen beans among a scattered group or about half a dozen words on a printed page. Similarly, the range of attention is rather narrow. We are unable to concentrate our attention at one time upon more than a very few items; the others remain vaguely within the outer fringe of consciousness. In order to bring many items into the clear field of attention, we must shift our attention, just as we shift the focal point of the retina, from point to point in successive mental movements.

Attention may be *volitional*, as when we deliberately concentrate our attention away from the book we are reading to the street noises outside. Oftentimes, though, it is *involuntary*, as when a clap of thunder or the shrill wail of a fire engine's siren forces our attention momentarily away from reading. At times, too, attention may be more or less habitual, due to a mental set or attitude, as when we are confronted by a definite task which engrosses our attention to the exclusion of everything irrelevant.

Some psychologists claim that attention is based entirely on the *strength of the stimuli* demanding attention; the strongest stimulus, they say, receives attention. While true

enough in very many instances, it is not universally true. It happens on some occasions that we deliberately turn our attention away from sights or sounds or thoughts which clamor insistently that we give heed to them; we may close our eyes or stop our ears to shut out an unwelcome sight or sound, or inflict discomfort upon ourselves to banish a certain train of thoughts.

There is more truth to the contention of some psychologists that attention is fundamentally a question of *interest*. That interest facilitates attention is natural. Interest, however, is only one factor which normally arouses attention; it is not the total explanation of attention. We may be intensely interested in a certain activity; if we realize, however, that our interest is misplaced or excessive, we can center our attention on something entirely different.

Some psychologists, especially those of a sensationalistic and associationistic trend of mind, advance the *drainage theory* of attention. According to this theory, only a limited amount of nerve energy can be utilized at any one time in perception. For example, when we listen attentively to the song of a robin, this limited amount of available energy in the brain is conducted into the auditory set of nerves and thereby drained away from the nerve paths of the other senses. This is an interesting theory, but it is highly speculative. Some such physiological arrangement may be present, but it would hardly account for those cases where we focus our attention on purely intellectual and voluntary operations or upon our own Ego. Just why the range of attention is so narrow in extent is very much of a mystery.

Behaviorists explain attention by *bodily attitudes*. Because the apparatus of a certain sense is definitely adjusted or 'attuned' to some stimuli, these stimuli produce sensations which force themselves into the focus of our attention. There is, of course, some truth to this claim, but it is only a part of the truth. It does happen at times that we hear certain faint sounds, because our hearing is 'keyed up' for some reason or other. But it is equally true that sometimes we deliberately induce bodily attitudes through antecedent attention, as when we purposely strain our ears to hear the faint ticking of the watch lying before us on the desk.

Whatever may be the ultimate explanation of the basic nature of attention, it is an obvious fact of experience that through attention we direct our cognitive processes, voluntarily or involuntarily, upon an object or set of objects and thereby become aware of their presence before the mind. *Without attention we cannot cognize an object.* To form an idea or concept of an object, therefore, we must focus our attention upon this object.

Abstraction

Attention is the first stage in the formation of an idea or concept. The next stage is that of *abstraction*.

Broadly speaking, abstraction is the intellectual process in which, through an act of selective attention, *we leave out of consideration one or more aspects of a complex total object so as to attend to some other aspect or aspects of this object.* An example will clarify the meaning of this

definition. In looking at the leaves of a chestnut tree, I concentrate my attention, let us say, upon their characteristic 'shape,' leaving out of consideration their color, chemical composition, biologic function, relation to the branches, etc. In separating mentally the 'shape' of the leaves from these other aspects of the complex total object of the 'leaves,' I have performed the mental process of abstraction. By applying this selective attention upon the 'shape,' I draw this 'shape' away (Lat., *abstrahere*, *ab* and *trahere*, to draw away from or out of) from the other aspects or items present; I do not deny the presence of these other items in the leaves, but I ignore them in my consideration and put them mentally aside. Again, I may direct my attention upon the 'color' of the leaves, or their 'chemical composition,' omitting the other items from consideration; this, too, is abstraction in the meaning defined.

Every act of abstraction involves an act of attention, but every act of attention does not involve an act of abstraction. In abstraction we select one item in a *total object* for special consideration ignoring the rest but without denying their presence in the total object. Abstraction thus involves an act of attention focused on the one item to the exclusion of other items. Of all the items present in the total object 'chestnut leaf,' I focused my attention solely on the 'shape.' We may, on the other hand, have attention without abstraction. We may, for example, concentrate our attention on a chestnut tree, and then turn our attention to an oak or an elm standing nearby. Chestnut, oak, and elm trees are distinct entities and do not form a 'total object' among

themselves; each has a separate existence of its own in nature, so that they are different 'total objects.' In abstraction, however, the various items exist together in the same 'total object' as a unit, and it is only *ideally or mentally* that the act of selective attention separates one item from the others and gives it special consideration. Attention and abstraction, therefore, are not identical processes in all respects. Abstraction is a species of attention, a particular type of attention.

Because of this mental separation of items through selective attention, we speak of *positive* and *negative* abstraction. The item selected for special consideration moves into the focus of attention, and we become aware of its presence in a clear and vivid manner. This act of attention is a positive act or process. The abstraction resulting from this act of selective attention is, therefore, a 'positive abstraction,' and the item thus mentally abstracted from the other items present in the total object is said to be 'positively abstracted.' The other items, not selected by the act of attention, thereby automatically move into the outer fringe of attention and are automatically separated or mentally dissociated from the selected item. By the very fact, for example, that we positively abstract the 'shape' of the chestnut leaf from the other items present, we also abstract these other items from the 'shape'; the separation of the one involves the separation of the others. Since the abstraction of the 'shape' is the result of a positive act of attention, the abstraction of the other items is a 'negative abstraction,' and they are said to be 'negatively abstracted.'

There are two forms of abstraction: *generalizing and isolating* abstraction. The formation of concepts cannot be understood without a thorough grasp of these two forms of abstraction.

Generalizing Abstraction

Generalizing abstraction is that form of abstraction in which we separate mentally, through an act of selective attention, *items which are common to a number of individual objects from those items in which these objects differ and then arrange the objects having the common items into a class as a unit.*

There are, for example, many kinds of trees — chestnut trees, oak trees, elm trees, apple trees, pear trees, maple trees, pine trees, etc. They differ in many items, but they also have certain items in common. If we concentrate our attention on the items they have in common, we find that all are ‘woody perennial plants having a single main stem or trunk arising from the soil, their tops consisting of branches and foliage.’ By leaving aside all the items in which they differ and considering only the items in which they are alike, we arrange them all into a single class and designate them as ‘trees.’ This is an instance of ‘generalizing abstraction,’ and by its means we have arrived at the *concept or idea* of ‘trees.’ The items contained in this concept of ‘tree’ are such that they can be applied to any single tree taken individually, such as the elm tree growing on the lawn in front of my house or the solitary apple tree growing in my back yard, and also to all trees taken

collectively as a class, no matter what their kind or number. The content of the idea 'tree,' as expressed in the definition given above, is an *identical and permanent content*, applicable to the whole class and to every member of the class. The content of the idea is thus universal in application, and such an idea is therefore said to be a *universal idea*, i.e., an idea which represents some common nature or attribute which can be applied to *a class as a whole* and to each individual of that class. The product of generalizing abstraction, therefore, is the universal idea.

The fact, whether there exists in the intellect anything like the process of generalizing abstraction, has long been a matter of dispute among English-speaking philosophers. John Locke (1690), in his *Essay Concerning Human Understanding*¹ claimed that he had a general (universal) idea of a 'triangle.' George Berkeley (1710) was convinced that he possessed no such wonderful faculty of abstracting ideas. "For myself," he says, "I find indeed I have a faculty of imagining or representing to myself the ideas of those particular things I have perceived and of variously compounding and dividing them.... The idea of man that I frame to myself must be either of a white, or a black, or a tawny, a straight, or a crooked, a tall, or a low, or a middle-sized man. I cannot by any effort of thought conceive the abstract idea above described."² He is convinced that there are no such things as abstract (general or universal) ideas.

Berkeley's contention is easily tested. Consider the idea of 'man' as advanced by Berkeley in the quotation just given. It is, of course, entirely concrete and particularized, not abstract and universal. And now consider the following

analysis of the idea 'man' as subjected to a process of selective attention and abstraction.

Human beings are individuals, and no two are altogether alike. They possess differences in color, weight, size, bodily formation, mental and emotional peculiarities, etc., which distinguish one human being from another. Some are, as Berkeley points out, white, some black, some tawny; some are straight, some crooked; some tall, some short, some middle-sized. Some are male, others female; some are vicious, others virtuous; some are healthy, others diseased; in age they range from infants to centenarians. Individual men are perceived in this manner and imagined in sense-images; perceiving and imaging in this manner is an everyday occurrence. So far, our selective attention has been directed toward the features in which individual men *differ*. But the mind does not stop with contemplating these individual differences; it can, and does, also focus its attention on the features in which the individual men *agree* and which they have in common. Focusing our attention on the features common to all men, we find that all men, no matter what their individual differences may be, possess a body which exists for itself, independent of all others; man is, therefore, a 'bodily substance.' Like the plants, men take in food, assimilate it, grow; man, therefore, lives and is a 'living bodily substance.' Like the brutes, man has external and internal senses which enable him to obtain sensory knowledge; man, therefore, is a 'sentient living bodily substance.' Unlike chemicals, plants, and brutes, men think, reason; *man, therefore, is a rational, sentient, living, bodily substance*. These features are not sensed or imagined, but

they are true features of man, and they are the features which all men have in *common* and which are *essential* to man as man, irrespective of all individual differences. Now, a 'sentient, living, bodily substance' is termed an 'animal,' and man is thus defined as a rational animal. The individualizing features have been left aside, and the common, essential features have been grouped together. By means of this process of selective attention we have 'abstracted' the common, essential features, ignoring, though not denying, the differentiating qualities, such as 'white,' 'black,' 'tawny,' 'straight,' 'crooked,' etc. The result was obtained by a process of *abstraction*. This definition of 'man' as a 'rational animal' can now be applied in all truth to every single man, because this thought-content is present in each individual; we are thus able to say 'George Berkeley is a rational animal.' But it can also be extended in its application to all men taken collectively as a group, as when we state that 'Man is a rational animal.' Now we have *generalized* the features common to all men, applying the thought-content 'rational animal' to all men as a class and to each individual of that class. We have performed the mental operation of a *generalizing abstraction*, and through it we have arrived at an idea of 'man' quite different from that of Berkeley. Berkeley's so-called 'idea' of man is no idea of all, but a sense-image. Ours is a true idea or concept, namely, the *intellectual representation* of 'man.'

The Chinaman and the Zulu, the Mohawk and the Inca, the Egyptian and the Greek, the Roman and the Englishman, the European and the American — all, individually and collectively, possess the same (not identical,

but like) common human nature or essence. The idea (concept) of this common nature or essence then also applies to all, individually and collectively, and is therefore a truly *general or universal idea*.

There is really nothing mysterious or wonderful about this mental power of abstraction. It is a commonplace thing, used every day in the week. Even children use it constantly. They soon learn to 'abstract' the features common to dogs, cats, horses, men, dolls, dresses, houses, etc. If they did not possess the power of abstraction, it would be impossible for them to point to an object or picture and designate it as a 'dog,' a 'cat,' a 'doll,' a 'house,' and so on; they recognize the individual thing as belonging to a definite class because of some common feature or features present in all members of that class.

We thus see that the process of generalizing abstraction is nothing more than a particular form of selective attention, and the product of this abstraction is the universal idea.

AFTER HAVING DESCRIBED THE PROCESS OF GENERALIZING abstraction which results in the formation of universal ideas or concepts, it is easy to find *evidence of its presence*.

We find this evidence in the *common vocables* or words existing in every language. Nouns and adjectives, in their usual forms, are all universal ideas. They represent items common to a class as a whole and to every member of that class. Among nouns we may mention at random ideas such as 'house,' 'watch,' 'pencil,' 'dog,' 'bird,' 'fly,' 'book,'

'orange,' 'cloud,' and so on. Among adjectives, 'red,' 'soft,' 'small,' 'metallic,' 'bright,' 'transparent,' 'fluid,' and so forth.

Every general *definition* represents a universal idea. The dictionary is a collection of universal ideas defined. Take the definition, for example, of a 'triangle' as 'a figure formed by three lines intersecting by twos in three points, and so forming three angles.' It makes no difference whether the individual triangles be equilateral, isosceles, right-angled, obtuse-angled, or scalene; the definition or idea fits each one individually and all of them as a class.

Scientific *nomenclature* and *classification* consist of universal ideas obtained through generalizing abstraction. The only reason why scientists are able to group the objects of their science into varieties, species, genera, families, etc., is due to the fact that they recognize the features common to many, so that they can be arranged into definite classes and subclasses. Without generalizing abstraction they could describe nothing but individuals.

Generalizing abstraction, therefore, is an ordinary fact of mental experiences found in young and old, in the illiterate and in the educated.

Generalizing abstraction appears in three degrees or grades: *physical, mathematical, and metaphysical*.

Consider again the instance of the 'tree.' My sense image of a 'tree' places before me, either in perception or in imagination, a single object clothed with all the individualizing circumstances of color, shape, size, time, and place. It is either *this* chestnut tree, or *this* oak tree, or *this* apple tree, and so forth. By comparing the various kinds of tree, I abstract those items *common to all 'trees,'* omitting

all the items peculiar to the single kinds of trees and to all individual trees. This degree of abstraction is *physical* abstraction.

It may be a question of leaving all sensible matter out of consideration and concentrating one's attention solely on the *magnitude, extension, and quantity* present in bodies. We then have abstract ideas of a 'point,' a 'line,' a 'plane,' a 'square,' a 'triangle,' a 'circle,' a 'square root,' etc. Our concept of a 'triangle,' for example, is not only divested of color, shape, size, and so on, but also of all materiality. This degree of abstraction is *mathematical* abstraction.

The highest degree of abstraction consists in this, that we divest things of all that distinguishes one kind of thing from another kind of thing (matter and spirit, sensible and supra-sensible, creature and God) and select only those items in which *all things* agree and which they have in common. Such abstract ideas will then apply to all things. Among these ideas are, for example, 'being,' 'substance,' 'good,' 'true,' 'cause,' 'actuality,' and so forth. This degree of abstraction is *metaphysical* abstraction.

Scholastics group these three degrees of abstraction under the common term of *formal abstraction*. They also speak of *total abstraction*. By the latter they understand the abstraction of the universal whole in progressive stages. For example, we abstract or extract the concept of 'man' from Joe and Jane, then that of 'animal' or 'sentient being,' then that of 'living being,' then that of 'substance.'

Isolating Abstraction

The second form of abstraction is *isolating abstraction*. It is the mental process by which, through selective attention, we mentally separate a particular feature from the subject in which it exists. The separation is mental, not physical. We concentrate our attention upon this feature, to the exclusion of others, and consider it in our mind as if it existed independently of a subject. The product of the isolating abstraction is the *abstract* idea.

Language is replete with abstract ideas. Such are ideas like 'whiteness,' 'brightness,' 'softness,' 'transparency,' 'humanity,' 'triangularity,' 'animality,' 'rationality,' etc. The difference between a concrete and an abstract idea should be fairly obvious. 'White' is concrete; 'whiteness,' abstract. 'Transparent' is concrete; 'transparency,' abstract. 'Man' is concrete; 'humanity,' abstract. 'Triangle' is concrete; 'triangularity,' abstract. Concrete ideas always imply a *subject* with an attribute. 'White,' for example, always means 'something white.' Abstract ideas consider the item mentioned *as if* it had *no* subject. The use of concrete and abstract ideas as predicates in sentences reveals their difference. We say that 'The rose is (something) white,' but we say that 'The rose has whiteness.' Or, 'Peter is a man,' but 'Peter *possesses* humanity (meaning 'human nature').' Again, 'The sun is bright' but 'The sun *has* brightness.'

When we turn our attention upon a *quality, attribute, or activity* existing in some thing and make a noun or substantive of it, thereby lifting it mentally out of the subject in which it is found and exists, we use isolating abstraction. By isolating such a quality, attribute, or activity from its subject, we treat the quality, attribute, or activity as

if it existed independently, as if it were a substance, and no longer a mere quality, attribute, or activity belonging to a subject; in other words, we *substantivize* or *personify* the quality, attribute, or activity.

This type of abstraction is very common in our mental operations. We perform the operation so frequently, that we even fail to notice the performance. Read the preceding and the present paragraphs carefully, and note the abstract ideas contained therein. Among them are 'attention,' 'quality,' 'attribute,' 'activity,' 'abstraction,' 'operation,' 'performance.' In nature, as actually existing, we have indeed an 'attending, active, abstracting mind or human being,' but there exists no such thing as 'attention,' 'activity,' or 'abstraction' by itself. We treat these realities as if they existed outside a subject, due to the substantivization of the process of isolating abstraction.

Scientific treatises swarm with abstract ideas of all kinds. Rather than mention the subject-plus-quality on all occasions, scientists simply substantivize the quality, when they desire to speak of the quality in which they are interested. Such a procedure is, of course, perfectly legitimate, so long as we remember that in actual existence the underlying subject is also present, even though not mentioned. Biologists thus speak of 'life,' 'growth,' 'nutrition.' Physicists speak of 'motion,' 'velocity,' 'vibration,' 'sound.' Mathematicians speak of 'magnitude,' 'extension,' 'triangularity,' 'number.' Psychologists speak of 'sensations,' 'appetency,' 'emotion,' 'thought,' 'perception,' 'abstraction,' 'intellection,' 'volition,' 'attention,' and so forth.

It is important to bear this fact about isolating abstraction in mind. Though the underlying subject of the isolated items is not mentioned, *the underlying subject is not denied but implied*.

We thus see that generalizing and isolating abstraction are two very important functions of the mind. They are the instruments which the mind uses to penetrate beneath the appearance of sense into the inner, hidden *nature* of things. They reveal, as Aristotle expressed it pithily, 'what a thing is.' The senses merely perceive 'how a thing appears,' but the intellect understands 'what a thing is.' A 'man,' viewed from the standpoint of the senses, is 'white or black or tawny, straight or crooked, tall or low or middle-sized'; viewed from the standpoint of the intellect, a 'man' is a 'rational animal.' The senses elaborate an image of 'man'; the intellect elaborates an idea of man.' Both the image and the idea are representations of one and the same object, 'man'; but the image is a sensory representation, while the idea or concept is an intellectual representation, and both representations are entirely different in character and content. The sensory image is the product of sensation and perception, the idea or concept is the product of abstraction and intellection.

The Idea or Concept

Intellection consists in the formation of ideas, judgments, and inferences. We must now turn our attention specifically to these mental items.

The *concept or idea*, as was stated before, is the intellectual representation of a thing; that is to say, it represents 'what a thing is.' How many *kinds* of things do concepts cover? How far do concepts extend in the range of objects?

For one thing, we have ideas of the objects of sense and of their attributes. I perceive, let us say, a 'white man,' a 'moving automobile,' a 'red flower,' a 'glowing sun.' Through the process of abstraction I evolve the ideas of 'whiteness,' 'man,' 'motion,' 'automobile,' 'redness,' 'flower,' 'glow,' 'sun.' Anything and everything, which affects the senses and is perceived can become the object of an idea or concept by means of generalizing and isolating abstraction. But we also have ideas of objects and attributes which are spiritual and immaterial and which are not perceived by the senses. Such are, for example, our ideas of 'soul,' 'God,' 'good,' 'evil,' 'truth,' 'error,' 'intellect,' 'thought,' 'infinite,' 'law,' and a host of others. It makes no difference in this connection whether such things actually exist or do not exist; the fact is simply that we have ideas of them. The sum of all the objects and attributes included within the range of our concepts is termed the *material object* of the intellect.

The common, *formal object* of the human intellect is that particular aspect of things in virtue of which they are the object just of the intellect, and not, for example, of the senses; it is that which is 'intelligible' in all things. There must be some intelligible content in all things, material and immaterial, finite and infinite, which represents a *common element* present in everything of which we can form ideas. The common, formal object of the intellect is *being*. The

only intelligible element in which all things (God and creature, material and immaterial, object and attribute) agree is that they are 'things,' 'beings.' *Being, thingness, whatness*, therefore, is the common, formal object of the intellect.

Philosophers make a distinction between the *primary* and the *secondary* formal object of the intellect. The 'primary' formal object is the proper, proportionate, direct, natural, and immediate object to which the intellect turns its attention and of which it forms its ideas; it is, one might say, that particular type of object which the human intellect, by its very nature and constitution, is 'made to know.' Anything else would be a 'secondary' formal object. Now, what precisely is the primary and what is the secondary formal object of the human intellect?

THE PRIMARY FORMAL OBJECT IS THE 'SENSIBLE,' BUT AS ABSTRACT and universal.

In saying that the primary formal object of the human intellect is the 'sensible,' we mean to state that the intellect is so constituted, that it derives its ideas directly and naturally from the *sense objects* presented in sensory experience. And now for the proofs.

First, normal and abnormal psychology reveal the fact that a very close connection exists between *nerve action* and intellectual activity. A normal functioning of the nervous system facilitates rational knowledge, while pathological disturbances interfere with the orderly processes of thinking. One need but remind one's self of the influence of

drugs and of cerebral injuries upon thinking, in order to realize the close connection between nerve action and intellectual activity. Persons blind or deaf from birth can form no adequate idea of color or sound; this fact is definite indication that the human intellect obtains its ideas by turning to the data presented by the external and internal senses.

Second, *consciousness* is witness to the same general fact. It is a common practice in the elucidation of difficult and abstruse problems to have recourse to images and analogies taken from sensible objects. Images and analogies can make abstract ideas clear only on the supposition that the intellect derives its concepts first and primarily from sensible objects. The primitive words of every language are concrete and sensible in character. Anglo-Saxon words, for example, are seldom abstract, but rather concrete, in form. Highly abstract technical terminology, such as is used in scientific and philosophical discussions, is the product of advanced culture and mental development extending over a period of centuries. Even technical terms show their sensible origin in their etymology. Mainly, however, our concept of immaterial and spiritual realities shows that our intellect derives its ideas naturally and originally from material and sensible objects since the terms are negative or analogical in their ultimate meaning. 'Immaterial,' for example, means 'not-material' and 'spiritual' means 'breath-like' (*spiritus*, breath). The only way in which we can express supra-sensible things is to use a sensible term and deny the limitations inherent therein, as when we say that 'the soul is immortal (not

mortal)' and 'God is infinite (not-finite).' This method of using images and analogies makes it plain that the primary formal object of the human intellect is the *sensible*, not the spiritual.

Third, our thinking has the tendency to be accompanied by images of some sort. Whether there is such a thing as 'imageless thought,' will be taken up later. The fact remains that images seem to run along with our concepts. If we think of a triangle,' we will probably find a faint image of a triangle present at the same time. If we think of a 'tree,' a 'fish,' a 'house,' a 'street,' a 'man,' etc., some sort of image of these things will in all probability accompany their ideas. It would take a distinct effort on our part to exclude these images, which would hardly be the case if they were foreign elements intruding themselves upon our consciousness. We must, then, conclude that the materials for the formation of ideas are presented to the intellect by the senses. The sensible, therefore, is the primary formal object of the intellect.

The primary formal object of the human intellect is the sensible, but the sensible as *abstract and universal*.

That we conceive the sensible as abstract and universal, should be clear from what has been said above concerning generalizing and isolating *abstraction*. Sensible objects are individual objects, no two of which are perfectly alike in all respects. If our ideas of sensible objects were concrete and individualized like these objects themselves, they would fit a single object only and could not be applied to a class as a whole and to each individual of that class. What I perceive in nature is 'this elm,' 'this oak,' 'this birch,' 'this pine,' etc.

They are single things perceived singly. There is no such thing in nature like a 'universal elm' or a 'universal tree.' By abstracting the features common to all elms and to all trees and expressing them in a single concept, I obtain the abstract idea of 'elm' and 'tree,' which designates 'what an elm is' and 'what a tree is.' I then extend the idea 'elm' to all elms and the idea 'tree' to all trees, so that these ideas have a universal application. Ideas thus express the *class-nature*, applicable to each and all; they are abstract and universal.

It is because of this character of abstractness and universality, that *words* and *language* are an *intelligible vehicle of ideas*. Words stand for ideas, and ideas stand for the class-nature of things. Because ideas are abstract and universal, the words symbolizing them convey knowledge from one intellect to another which is permanent, unchangeable, and essential, independent of the changing individual things from which these ideas were originally derived. Scientific works would have no lasting value, if the scientists had not abstracted the common and essential features of objects and activities, universalized the information contained in their ideas, and then expressed them in words which are also abstract and universal. Words partake of the nature of the ideas which they represent.

We thus see the truth of the statement that the primary formal object of the human intellect is the sensible, but abstract and universal.

IT FOLLOWS AS A NECESSARY CONSEQUENCE THAT WHATEVER IS *supra-sensible*, spiritual, and extra-mundane is not the primary but the *secondary formal object* of the human intellect. Among such objects must be included 'soul,' 'spirit,' 'God,' and all that pertains to them.

Consider our thinking experience. We experience far greater difficulties in forming concepts of these types of being than we do of sensible objects. It is, for example, more difficult to arrive at a comprehensive and clear idea of the 'soul' than of a 'tree' or a 'triangle.' Ideas of spiritual realities never enter the mind spontaneously, but by indirection and inference; we draw conclusions concerning them from the objects and facts of sense presented in sensory experience. Again, our ideas of spiritual realities reveal their ultimate *sensory origin* by the fact that their basic meaning is derived from concepts having sensible significance. We have an example, mentioned before, in the word 'spirit' which originally meant 'breath.' In thinking of God and His attributes we start with the perfections of creatures (material, finite, powerful, knowing, etc.), deny the imperfections (immaterial, in-finite), and then ascribe to Him these creatural perfections in a boundless manner (all-powerful, all-knowing). Our ideas of purely spiritual beings and realities thus being acquired by a direction of the mind to the ideas abstracted from sensible objects and realities, it is evident that the supra-sensible is not the proper, direct, immediate, and natural object of the intellect of man, but its secondary object.

The present discussion proves the truth of Aristotle's famous pronouncement: *There is nothing in the intellect*

which was not first in the senses. Our knowledge begins with sensory experience and ends up in intellectual ideas.

Idea and Image

Berkeley, it will be remembered, confused his 'image' of man with the abstract and universal 'idea' of man. The same confusion occurs frequently among modern psychologists. It is advisable, therefore, to point out the main difference between ideas (concepts) and images (phantasms).

In speaking of 'image' and 'phantasm,' we include both the 'percept' of the central sense, as synthesized from the sensations aroused by stimuli in the presence of a sense object, and the 'image' of an object which is revived in the imagination in the absence of the original sense object. For the sake of convenience, the terms 'idea' and 'image' will be used.

For one thing, the image is always concrete and individualized, fitting at the most only a few objects at one and the same time; and if the image is very clear and detailed, it can fit but a single object. The reason is obvious. An image is taken from a sensible object and represents this object; an object, however, is always concrete and individual. We indeed have what are called 'general images,' such as the general image of a cat, a fish, a house, a boat, and so forth; we retain in such a general image only the most striking features of a particular set of objects, so that our image is more or less schematic. It is impossible, however, to form an image which would resemble all the

members of even a single class. We cannot, for example, form the image of a 'man' which would adequately fit at the same time a baby, a girl of eighteen, Napoleon, George Washington, a Negro woman, and an Indian. Much less would the single image of an 'animal' fit such heterogeneous types of animals as a spider, a snake, an ostrich, a shark, an elephant, and an amoeba.

We experience no such difficulty in applying an idea to the different kinds of individuals and classes, because the idea is *universal*. Our idea of 'man' as a 'rational animal' fits all individual human beings without exception, no matter what their age, sex, race, color, or personal characteristics. Similarly, our idea of 'animal' as a 'sentient living bodily substance' fits all the heterogeneous types of animals mentioned above.

Another difference is this, that an image becomes very *vague and indistinct with complexity and minuteness of detail*, while the idea remains clear and distinct. It is not difficult to form an image of 5 trees in a row; but it is utterly impossible for me to form an image of 50 (not 49 or 51) trees in a row. Yet my idea of 50 or of 5,000,000 trees is just as clear to me as my idea of 5 trees. Again, I cannot form an image of a geometrical 'lines which has only length and no depth or width; but my idea of such a 'line' contains no depth or width, as my definition of a line shows.

Finally, in many instances we have very clear ideas of things, but we are incapable of forming any *reasonable image* of them. Since we speak of such things as 'economics,' 'law,' 'virtue,' 'soul,' 'life,' 'God,' 'will,' 'knowledge,' 'ignorance,' 'death,' 'inference,' 'abstraction,'

‘psychology,’ etc., and even define them, we certainly have ideas of them. If we search our mind, however, we find no proper image of such ideas. Or, can we invest ‘abstraction’ with anything like shape, weight, size, color, sound, and similar qualities, so prominently present in our images? To put this question is to answer it.

Experimental psychology also has supplied evidence which shows that ideas are different from images. If ideas are images, then it must be impossible for ideas and images to become *separated in experience*. But they do occur separately in temporal sequence. Laboratory experiments, made to determine the time required for a meaning (idea) and for visual or kinesthetic images to appear relative to the same object, definitely show that ideas and images do not appear simultaneously. The images appear later than the meanings or ideas.³ This time difference proves that ideas and images are different as entities.

Pathology also furnishes evidence along these lines. In the chapter on the central of synthetic sense, instances were cited where damage to the cerebrum caused serious interference with the operations of this sense. Persons so afflicted did not recognize an object or a picture or a drawing placed before them; the image was present, but it had no meaning for them, so that they could not state what the image represented. They had, however, clear ideas of these things; because, when asked about them, they talked intelligently and understandingly concerning these things, thereby showing that they knew ‘what the thing is,’ even though the image itself conveyed no meaning to their mind. Ideas, therefore, must be distinct from images.

From the evidence adduced it should be apparent how utterly erroneous is the view of James Mill, as expressed in the following passage: "If I say I have the idea of a horse, I can explain distinctly what I mean. I have the ideas of the sensation of sight, of touch, of hearing, of something with which the body and actions of a horse have impressed me. These ideas combined, and so closely, that their existence appears simultaneous and one. This is my idea of a horse."⁴ On the contrary, this is not an idea, but an image.

The Judgment

Ideas lead to judgments. A judgment is an *act of the mind pronouncing the agreement or disagreement of ideas among themselves*; or, to express the same meaning in different words, it is an *act of the intellect affirming or denying one idea of another*.

The judgment always appears in one of two ways: it will either *affirm* or *deny*. In stating that 'The rose is a flower,' I affirm the agreement between the two ideas 'rose' and 'flower.' And in stating that 'The whale is not a fish,' I deny the agreement (or, affirm the disagreement) between the two ideas 'whale' and 'fish.'

Psychologically, the following stages occur in the intellect in the formation of a judgment: two ideas are presented by the intellect to itself for consideration; the meanings of the two ideas are grasped and understood separately; these meanings are compared with each other; the intellect perceives their mutual agreement or disagreement; then follows the mental expression or

pronouncement of their mutual agreement or disagreement, and this pronouncement is the judgment proper. Here is an example. The two ideas 'man' and 'animal' are presented to my intellect. A 'man,' I understand, is a 'rational, sentient, living, bodily substance,' and an 'animal' is a 'sentient, living, bodily substance.' I now compare these two meanings with each other. I perceive that the thought-content of 'animal' as a 'sentient, living, bodily substance' is included in the thought-content of 'man' as a 'rational, sentient, living, bodily substance,' and in so far both thought-contents are in agreement with each other. I now express or pronounce this agreement in the mental judgment that 'Man is an animal.' If I were to compare the two ideas 'whale' and 'fish,' I would go through the same procedure, but I would perceive that the thought-contents of 'fish' does not agree with that of 'whale' (for the whale is a mammal, not a fish), and I would pronounce their disagreement by the judgment that 'The whale is not a fish.' Depending upon the ideas compared, my judgment will contain an affirmation or a denial.

Three elements, then, enter into the composition of a judgment: two ideas, and the mental act pronouncing their agreement or disagreement. One idea, the subject-idea, is the one 'about which' something is said; and the other idea, the predicate idea, is the one 'which is said about' the other. The two compared ideas are the matter of the judgment, because they are the materials which enter into composition in the judgment. The act pronouncing their agreement or disagreement is the *form* of the judgment, because this pronouncement constitutes the very essence of

the judgment as a judgment, distinguishing it from the concept and the inference. From the standpoint of its 'matter,' the judgment is a composition of two distinct elements, the ideas; from the standpoint of its 'form,' the pronouncement, it is a single intellectual act fusing the two ideas into one or separating them from each other. Such is the nature of the judgment.

The *foundation* of the judgment consists in the *intellectual insight into the logical relations* which exist between the subject-idea and the predicate-idea. The mind perceives that the subject-idea is contained (or not contained) within the class-extension of the predicate-idea, and that the thought-content or comprehension of the predicate-idea is contained (or not contained) within the thought-content or comprehension of the subject-idea. Correspondingly, the intellect pronounces its judgment of agreement or disagreement.⁵ These relations, it will be observed, are of a *logical* nature and entirely different from the sensible relations which exist in the associative bonds present between images, due to contiguity in space or time, similarity, or contrast. The judgment is not a connection between images, but a composition of ideas.

Judgments are not just private exercises of the intellect combining and separating ideas. Ideas being representations of things, they convey to us the meaning of the things for which they stand, and in so far the judgment is a *representation of reality*. Every judgment presupposes and implies the existence of reality, and this is known as the 'existential import' of the judgment.

Judgments thus contain within themselves the *claim of truth*, although the fact is also acknowledged that at times they may be false. *Truth* and *error* lie in the judgment. When the intellect compares two ideas with each other and pronounces an agreement or disagreement between them, it actually compares two things with each other and judges about their agreement or disagreement among themselves as they are in reality. Hence, if a judgment coincides with reality, it is true; if not, it is false. In consequence of this relation between ideas and things, we are not at liberty to judge as we please. Because in reality things are (or are not) so and so, the mind has no choice but to represent reality as it actually is or, at least, as it judges it (perhaps erroneously) to be. The mind *accepts* the truth, it does not make it; and it accepts the truth, because it is determined by the objective evidence furnished by reality itself.

The judgment, therefore, is the product of an intellectual insight, and *not of the will* and its deliberate choice, as Descartes and Malebranche claimed. Nor are some fundamental judgments dictated by blind *instinct*, as Thomas Reid maintained. Emmanuel Kant also is wrong, when he asserted that we judge as we do because of *innate mental categories* which have no bearing on reality as it actually exists. These theories are contrary to all the evidence of experience. It is only in the case of *doubt* that the will, for practical reasons, may demand the assent of the intellect to a judgment.

The Inference

The intellect forms concepts; it forms judgments. It has also a third type of operation: it forms *inferences or ratiocinations*. Inferences are the products of the reasoning power of the intellect. Inference, in general, is defined as the *process by which, from certain truths already known, the mind passes to another truth distinct from these but necessarily following from them.*⁶

We find that the basic *construction* of an inference contains the premises, the truth of which is already known, and the conclusion which follows from the premises with necessary consequence. Because the premises are true, the conclusion must also be true. The conclusion is contained implicitly in the premises; in drawing the conclusion, we merely state explicitly what the premises stated implicitly. The intellectual *insight* into the logical *relations* existing between the premises on the one hand and between the conclusion and the premises on the other constitutes the psychological factor which compels the intellect to draw the conclusion and to acknowledge its truth and validity.

As a typical illustration of an inference, we give the following example of a categorical syllogism:

All residents of the fifth ward vote in the fifth-ward
school;
Steven S. Jones is a resident of the fifth ward;
Hence, Steven S. Jones votes in the fifth-ward
schoolhouse.

The logical relations between the premises and between the conclusion and the premises are clear. *If* (or, *since*) all

residents of the fifth ward vote as directed; and if (or, since) Steven S. Jones, upon inquiry, is found to be a resident of the fifth ward; *therefore* it follows with logical necessity that he must vote in the fifth-ward schoolhouse. No other conclusion can be drawn from these premises, because this conclusion is implicitly contained in the premises.

Psychologically, the knowledge of the premises must *precede* the knowledge of the conclusion, with a priority in the order of *nature* and in the order of *time*. The conclusion depends for its truth and validity on the truth and validity of the premises; without the premises the conclusion cannot be drawn. That, however, which depends on another for its existence must, in its very nature, succeed and not precede this other upon which it depends. Hence, since an inference is a question of knowing, the knowledge of the premises must precede the knowledge of the conclusion, so far as the elements of the inference are concerned. And since it takes a certain amount of time to cognize each premise and the conclusion individually and the logical relations existing between them, the knowledge of the conclusion must be temporally later than the knowledge of the premises, even though the final insight into their mutual relationship is an instantaneous act of the intellect.

The premises are the foundation of the conclusion; they contain the conclusion implicitly. It is only because this necessary relationship between the premises and the conclusion is understood by the intellect, that we are entitled and compelled to draw the conclusion. Premises and conclusion form a *constructional* and *logical unit*. In order, then, that the intellect be able to make the inference,

the intellect must embrace in a single psychological act the premises and their mutual relationship; otherwise the intellect would not have the insight that the conclusion follows with necessary force from the logical relation of the combined premises.

Some modern psychologists have attempted to explain the reasoning process as a *fusion of images*. Applied to the example of the categorical syllogism given above, the process might be conceived to go along the following lines: an image of a section of the city, containing a school building; the image of a man (Steven S. Jones), included in the general image of the first image; the image of the man fusing with the image of the schoolhouse, as the man enters the building. It takes but a moment's reflection to see how utterly inadequate such an explanation really is when compared with the actual process of an inference. The intellectual *insight* into the *logical relations* between the judgments is the basis of the inference, not the mere juxtaposition and fusion of images. It is on the basis of the *abstract principle* that 'What is true of the logical whole must also be true of every part of that logical whole,' that I draw the conclusion that Steven S. Jones must cast his vote at the designated place. All residents of the fifth ward form a class, a logical unit or whole, and what is true of this whole class must be true of every one belonging to this class; Steven S. Jones belongs to this class, is a member of this class as a logical unit or whole; and so he must vote in the place assigned to the class. We have here a general principle applied to an individual instance, not a mere fusion of imaginal elements.

Intellectual activity, or intellection, is of a *totally different order* than sensory activity, because sensations and images alone cannot account for the formation of ideas, judgments, and inferences. Nevertheless, intellection would be impossible without antecedent sensory knowledge, because the senses furnish the raw materials from which the intellect abstracts ideas and then proceeds to utilize ideas in the formation of judgments and inferences. Sense and intellect are not foreign to each other. Man is a sensory-intellectual being, a rational animal, an *integral organism*.

Summary of Chapter XII

The rational processes of man's mental life consist of *intellection* and volition.

1. *Intellection*. It comprises three distinct processes: the formation of ideas or concepts, the formation of judgments, and the formation of inferences.

2. *Attention*. It is the direction of the cognitive process toward an object, activity, or thought. Some psychologists base attention on the 'strength of the stimuli'; others, on 'interest.' Some favor the 'drainage theory' as an explanation of attention. Behaviorists attempt to explain attention by 'bodily attitudes.' Without attention we cannot cognize an object.

3. *Abstraction*. It is the mental process in which, through an act of selective attention, we leave out of consideration one or more aspects of a complex total object so as to attend to some other aspect or aspects of this object. Abstraction is either *positive or negative*.

4. *Generalizing Abstraction*. It is that form of abstraction in which we separate mentally, through an act of selective attention, items which are common to a number of individual objects from those items in which these objects differ, and then arrange the objects having the common items into a class as a unit. The product is a *universal idea*, applicable to the class as a whole and to each individual member of that class. Evidence for the existence of universal ideas is found in the common vocables of language, in definitions, and in scientific nomenclature and

classifications. There are three degrees or grades of abstraction: physical, mathematical, and metaphysical. Abstraction may be either *formal* or *total*.

5. *Isolating Abstraction*. It is that form of abstraction in which, through an act of selective attention, we mentally separate a particular feature from the subject in which it exists and consider it as if it existed independently of a subject. The product of this abstraction is the *abstract idea*.

6. *The Idea or Concept*. An idea is the intellectual representation of a thing. The material object of the human intellect is the sum of all the objects and attributes included within the range of our concepts. The common, formal object is that particular aspect of things in virtue of which they are the object just of the intellect, and not, for example, of the senses. The formal object of the intellect is 'being' in general. The primary formal object of the intellect is the proper, proportionate, direct, natural, immediate object to which the intellect turns its attention and of which it forms its ideas; anything else would be a secondary object.

The primary formal object is the *sensible*, but *abstract* and *universal*. The secondary formal object of the intellect is the *supra-sensible*, spiritual.

7. *Idea and Image*. Images are concrete and individualized; ideas are universal. Images become vague and indistinct with complexity and minuteness of detail, while ideas remain clear and distinct. We have clear ideas of many things of which we are incapable of forming any reasonable image.

8. *The Judgment.* It is an act of the mind pronouncing the agreement or disagreement of ideas among themselves. It appears as an affirmation or denial. It contains three elements: two ideas, and the mental pronouncement of their agreement or disagreement; the ideas are the 'matter,' and the act of pronouncement is the 'form,' of the judgment. The foundation of the judgment consists in the *intellectual insight into the logical relations of the subject and predicate.*

9. *The Inference.* Inference is the process by which, from certain truths already known, the mind passes to another truth distinct from these but necessarily following from them. Inference is based on the *intellectual insight* into the *logical relations* existing between the premises and conclusion. Psychologically, the knowledge of the premises must precede the knowledge of the conclusion, with a priority in the order of nature and in the order of time. The intellect must embrace in a single psychological act the premises and their mutual relationship.

6 The various types of inferences are treated extensively in Logic. In psychology we presuppose that the student is familiar with these types. See the author's *The Science of Correct Thinking*, Parts 3 and 4

Chapter 13

THE ORIGIN OF IDEAS

MAN HAS ALWAYS CONSIDERED HIMSELF SUPERIOR TO THE BRUTE. Evidence for this superiority was found in man's power to think. When philosophy came into existence in ancient Greece, the problem of the nature and origin of ideas in the human mind was bound to arise sooner or later. The problem received a sharp impetus under Socrates. Plato, Socrates' disciple, made it the very heart of his philosophic system. And from that time on up to the present day, the problem has engrossed the attention of the greatest thinkers. The problem can be formulated briefly as follows: If ideas are essentially different from sensations and images, *how do ideas originate?*

In the preceding chapter it was shown that ideas are fundamentally distinct from sensations and images because of the *abstract, universal* character of ideas. Nevertheless, ideas are derived somehow from the sensible and are rooted in the sensible. This truth will receive confirmation from a study of the various systems of philosophic thought which have been advanced in the course of the centuries as an explanation of the origin of ideas.

Roughly, all theories on the subject can be grouped into three main classes: the theory of *innate ideas*; the empiricist or sensationalist theory; and the *peripatetic or aristotelian-scholastic theory*. The first group overemphasizes the function of the rational mind in the formation of ideas; the second overemphasizes the function of the senses; the third seeks to emphasize the function of both the rational mind and the senses in proper proportion. The problem will be treated along the lines indicated by these groups of theories.

Plato's Ultra-Realism

Plato (427-347 B.C.) was aware that the world of sense and sense objects is in a state of continuous change. From the fact of continuous change he concluded that there is nothing real and stable in the sense world. The universal ideas, *however*, have a content which is stable, real, unchangeable, eternal; the knowledge acquired through universal ideas is truly 'science.' Unless we are willing to admit that the scientific knowledge acquired through universal ideas is an illusion and a fiction, these ideas must be the representation of objective reality; and since the reality of the sense world is always changing and not eternal, it cannot be the reality of the sense world which is represented in the universal ideas. Hence, the existence of universal ideas in the human minds demands the existence of a supra-mundane world of *pure essences*, which are stable, real, unchangeable, and eternal and of which the

universal ideas of man are a true representation. These pure essences Plato called *Ideas*.

The Ideas alone have reality in the strict sense; they exist as real entities (noumena) apart from the world of sense (phenomena). The objects of the sense world are but faint, changing replicas or imitations of the eternal, unchanging Ideas; the Ideas are the eternal prototypes or exemplars of the objects of the sense world. The universal ideas of the human mind are true representations of these noumenal Ideas and cannot have their origin in the changeable and changing objects of this visible universe. It follows, according to Plato, that men's souls must have had a *pre-existence* in a former life in the noumenal world, where they contemplated the Ideas as these Ideas existed in themselves. On being united to the body in its present earthly existence, the soul forgot the knowledge of the Ideas, but the universal ideas thus acquired slumber in the soul until awakened; they lie *innate* in the recesses of the mind. For every object existing in the universe (tree, dog, sky, house, rose, etc.) there exists a corresponding Idea in the noumenal world. On seeing such an object in the present life (some individual tree, dog, etc.), we *remember* what we have known before and have forgotten: the innate slumbering universal idea is awakened and brought to consciousness. Hence, Plato's theory of innate ideas is also called the *theory of reminiscence*.

Criticism. For one thing, Plato supposes that the connection between body and soul in man's earthly life is *forced* and *unnatural*; the relationship between the two is *extrinsic*, similar to the relationship between a horse (body)

and its rider (soul). In this view, death should be a welcome event, a release for the soul from the imprisonment in the body. We know, however, that man dreads death. Man is by nature, as all evidence proves, a *psycho-physiological integral organism*. The dread of death shows clearly that the union of body and soul is natural. If their union were merely extrinsic, it is inexplicable how the union of the body with the soul could blot out the knowledge of the Ideas formerly contemplated, because the body could not possibly influence the inner activities of the soul.

Aristotle opposed Plato's theory on the grounds that it is poetic and fantastic and contrary to the *testimony of consciousness*. If we actually had a former existence, the awakening of the innate universal ideas should also revive the memory of this previous existence itself. But we have no such memory. The theory is pure assumption on the part of Plato.

Finally, in the foregoing chapter it was pointed out how we acquire our universal ideas from sensible objects through a process of *abstraction*. There is no need to have recourse to a noumenal world of Ideas and a previous existence in order to explain a process of knowledge which is as natural to man as sensation and perception.

Descartes' Ultra-Spiritualism

R. Descartes (1596—1650) taught that man's body and soul, though united, are two intrinsically independent substances. The essence of the soul is *thought* or 'thinking,' and the essence of the body is *extension*, and the two have

nothing in common. There can be no cognitional communication between body and mind, because the disparity between them is too great. The body is merely a machine (Chap. 10). 'Corporeal movements' reach the brain, and at the *occasion* of their presence the mind produces the ideas or representations of external and extended objects entirely in itself and by itself. Descartes denied the necessity of innate ideas which would be something distinct from the intellect itself. Because the intellect is innate to man, the ideas of the intellect are also innate, in the sense that a disease is innate to the man who is born with the disposition for this disease. The intellect, according to Descartes' theory, is the exclusive cause of all knowledge. Descartes thus considered ideas to be present in the mind from the beginning as 'dispositions,' and these dispositions are not derived from sense objects; ideas are *potentially* existing and subsequently become actual. His theory amounts to innatism.

Most of Descartes' followers assert that at least some fundamental ideas are innate, such as the ideas of 'God,' our own 'existence,' 'good,' 'evil,' 'free will,' and others. We have a 'habitual' knowledge of these, and this knowledge becomes 'actual' when the intellect turns its attention to these innate 'forms' of knowledge.

Criticism. Descartes placed an *ultra-spiritualistic* interpretation on the mind and an *ultra-mechanistic* interpretation on the body; the result was an ultra-dualism in the concept of 'man' which made it impossible to explain human intellectual knowledge in a natural manner. Descartes had no right to restrict the essence of the mind

to 'thought.' If the activities of man are such that the triple functions of *vegetancy*, *sentientcy*, and '*thinking*' are integrated operations of one and the same psycho-physiological *organism*, then Descartes committed an unpardonable error in limiting the essence of mind to 'thought' alone. That man is an integral organism is amply proved in the preceding chapters. Descartes' ultra-dualism is thereby disproved and with it the necessity of trying to explain the origin of our ideas through innatism.

All bodily and sensory functions are accompanied by *coenesthetic* (common general organic) sensations of some sort, making us aware of the body and bodily conditions as our own. Such sensations always involve an obscure feeling of the existence of the 'Ego'; the origin of the idea of the 'Ego' is thus explained, so that there is no need to consider it as innate. As for the ideas of 'God' and other supra-sensible objects, we have already seen that they are analogous ideas developed from ideas derived from sensible objects by heightening their perfections and denying their imperfections.

From all that has gone before, it should be clear that the *sense organs* are not mere mechanical structures and contrivances. They are *vital instruments* of knowledge which contribute actively their own part to the production of knowledge. Since they are extended organs, sensible objects can affect them through stimuli; since they are vital organs, they can respond vitally to the stimuli and furnish a cognitional representation of the objects in perception. Through abstraction from these sense representations the

intellect, organically united to the body and its senses, can *form ideas*. Nothing more is needed.

The Monadism of Leibnitz

G. Leibnitz (1646—1716) tried to overcome the ultra-dualism of Descartes in a unique way. All beings consist ultimately of *monads*. A monad is an elementary individual being, psychical or spiritual in nature. God is a monad; spirits are monads; the human soul is a monad. Even physical being consists ultimately of monads; thus, the body of man is a system of monads. There is *no interaction* between the single monads. All possess the power of representation,' and each monad in its representation mirrors within itself whatever takes place in all other monads throughout the universe; some do it consciously, like the mind-monads, others unconsciously, like the body-monads. Monads are 'windowless,' so that no knowledge is acquired from with-out but is developed from within. All ideas, therefore, are innate, present from the beginning as dispositions or 'natural virtualities' (*virtualités naturelles*) until evoked into actuality in the consciousness.

Criticism. Monadism is a *gratuitous* theory, artificial in the extreme, without any foundation in fact. The existence of such a universe of monads is a pure assumption. It disrupts the human organism into an aggregate of independent individual monads. It is disproved by the existence of the *nervous system* in man, which centers in the cerebral cortex as the evident center of sensory knowledge in response to stimuli reaching it from the

peripheral *organs*. Monadism leads to *solipsism*, that extreme form of subjective idealism which maintains that man can know nothing but his own subjective internal mental states, without the possibility of ever knowing whether anything objective corresponds to his ideas.

Ontologism

Ontologists, chief among whom are Malebranche (1638—1715), Rosmini (1797—1855), and Gioberti (1801—1852), assert that God and the divine Ideas are the primary objects of the intellect, and the *first act* of the intellect is the *intuition of God*. They base their view on the grounds that material objects can make no impression on an unextended intellect; the intellect, therefore, can derive no ideas from them. The intellect is also too imperfect to derive ideas out of its own nature as such. It beholds them in another spirit, the Infinite Being, whose Ideas are the types and exemplars of all created things. The intellect intuits the Ideas of God and in them acquires a knowledge of creatures. This intuition is possible because God is united to the souls of men in such a manner that one can say that He is in truth ‘the place of spirits.’

Criticism. If God and the divine Ideas were really the primary object of our intellect and the object first known by it, so that we behold the objects of the sense world in Him and in His Ideas, we should be *conscious* of this tremendous fact of experience. Needless to say, we are not. Again, if this supposition of the ontologists were true, the existence of God would be indubitably certain to man; doubt would be

as impossible in this respect as the doubt about our own existence. Experience, however, shows that we must prove God's existence to our own satisfaction from the facts discovered through a study of the universe. Finally, while ontologists assert that we do not intuit the substance of God, but God and His Ideas only in so far as they are in relation to creatures, this distinction is invalid. In God everything is one and the same infinite reality. To behold the Ideas of God means to behold God's *infinite essence* and substance. In that case, however, our ideas of God should be direct and positive, not indirect, analogous, and by negation.

Kant's Transcendental Criticism

Immanuel Kant (1724—1804), alarmed at the trend of thought manifested by the sensationalism of English philosophy, attempted to revindicate the validity of human knowledge and free it from the bane of skepticism prevalent since David Hume. He accepted without question the ultra-realism of Descartes and took as his starting point the principle that the mind of man can know only its own internal states and cannot go outside and beyond the limits of consciousness. He considered it to be the essential error of all previous philosophic systems that they endeavored to make the mind conform to the objects; he would reverse the principle and make the objects conform to the mind. His critique or criticism, therefore, intended to find out whether there *existed a knowledge independent of experience*. *Empirical* knowledge has its sources in

experience (*a posteriori*), while knowledge independent of experience has its sources in the mind (*a priori*). Correspondingly, our ideas will originate either in the mind and be innate or will originate in experience and not be innate. Have we an *a priori knowledge*? Kant is convinced we have.

According to Kant, experience can reveal nothing to us except what is *individual and contingent*; it never reveals anything that is strictly universal and necessary. If, then, our judgment at any time is thought with *strict necessity and universality*, such knowledge cannot have been acquired through experience but must be *a priori* and must proceed directly *from the mind itself*.

Kant admits the existence of noumena or things-in-themselves in the external world, and they affect the senses. The sense faculty responds with an 'intuition' or perception. These impressions are unarranged, chaotic. The chaotic 'manifold' of sense impressions must be arranged in a certain order by means of *two innate sense-forms, namely, space and time*. These forms are present in the mind antecedent to all experience. 'Space' and 'time' are in no way attributes of the things-in-themselves, but are *mental forms* which condition the perception of the things-in-themselves, so that they *appear* as arranged in the order of 'space' or in the order of 'time.' Since all things appear in this double order, 'space' and 'time' are universal and necessary conditions of sense-perception and as such must exist *a priori* (innately) in the mind. The physical objects themselves, the noumena or things-in-themselves, are, so far as we know, spaceless and timeless. We can know

nothing at all about the noumena, because we never perceive them directly. What we 'perceive' and know, therefore, is nothing more than the *appearances or phenomena* of things, and these are subjective in character, possibly without any resemblance to the things-in-themselves. The external, physical world remains forever an unknown X.

Passing from sense-intuition to *intellection* proper, Kant also finds a number of *a priori* forms of the pure understanding, and these he terms the *categories*. According to Kant, to think is to judge. When, therefore, we find judgments that are contingent and particular (e.g., 'This table is square'), they result from experience and are *a posteriori*; but when we find judgments which are necessary and universal (e.g., 'The sides of a square are equal to one another'), they must be the result of an *a priori* element or 'form,' namely, the 'category.' These categories express the necessary and universal relation which exists between the subject and predicate of a necessary and universal judgment or proposition. There are twelve such relations, and for each relation there exists a corresponding innate *a priori* category. They are: unity, plurality, totality; reality, negation, limitation; subsistence and inherence, causality and dependence, reciprocity (active and passive); possibility and impossibility, existence and non-existence, necessity and contingency.

These categories are *empty forms* of intellectual knowledge. The contents of intellectual knowledge must come from experience. After the 'manifold' of sense impressions is molded and arranged by the forms of 'space'

and 'time,' the categories are applied to these sense intuitions; the result is universal and necessary intellectual knowledge. One must remember, however, that this intellectual knowledge never penetrates to the noumena or things-in-themselves, but only to the *phenomena* or appearances. Noumenal knowledge is simply impossible. What the physical, noumenal world is like in itself, is forever excluded from the ken of the human mind.

Reason, in its inferences, leads us to *three fundamental ideas*: the idea of the *soul*, the idea of *matter* or the totality of phenomena, and the idea *God*. As such, these ideas are mere *a priori forms* of the mind and pertain solely to phenomena, having a regulative function only. They are indeed the highest 'forms' of the mind, but they are nothing more than 'forms,' on a level with the forms of 'space,' 'time,' and the 'categories.' Reason, therefore, cannot prove the existence of the soul, of the world, and of God as entities independent of the mind. It is only from the moral law that we know that the soul, matter, and God actually exist; *intellectual* knowledge reaches only as far as the phenomena.

Summing up Kant's doctrine, we find that man is *incapable of transcendent knowledge*; his knowledge cannot contact the noumenal but only the phenomenal. Man's knowledge is governed completely by *transcendental* (i.e., *a priori*, mental) *forms*. Kant's theory is a *transcendental idealism*.

Criticism. Entire books have been written on Kant's theory of knowledge. Kant's views led to the great systems of idealism which flourished in the 19th century. They have

had their day. As a criticism of his theory, we wish to stress the following points.

First, Kant's final conclusion was that our intellectual knowledge is *intrinsically illusory*. The intellect can know nothing of the things-in-themselves as they exist in the world around us; it can judge only of *phenomena*, and the phenomena reveal only the appearances, *not the reality*, of things as they impress the senses. But the intellect and its operations do not belong to the world of phenomena, because they do not affect the senses; they are an integral part of the mind itself. Since they cannot be phenomena, they must be noumena, things-in-themselves. Kant presumes to give us a thorough description of the intellect and its operations. Either, then, Kant actually did acquire a valid knowledge of noumena, notwithstanding the fact that he claimed we can never know the noumena; or, since all noumenal knowledge is impossible and illusory, his entire theory of the intellect and its operations is illusory and therefore false. In either case his theory breaks down.

Second, Kant maintained that a *physical world* of things-in-themselves, even though we can know nothing about it, actually exists. He assumes its existence on the grounds that the impressions made on the senses must be *caused* by external objects. Later on, however, he asserts that the concepts of 'causality' and 'causal dependence' are mere categories, and categories are but 'empty forms' contributed by the mind and without objective validity. Either, then, the category of 'cause' and 'effect' applies validly to noumena and is not an *a priori* mental form at all; or, if it is an *a priori* form, Kant is inconsistent in concluding

from the existence of sensations to the existence of a noumenal world. Besides, Kant assures us that the noumenal world of things-in-themselves is a *chaotic manifold*. In giving us this important information, he claims to know something about the *objective reality* of the world distinct from phenomena. And here again he is inconsistent.

Third, Kant's theory is *contrary to the science of psychology*. He maintains that 'space' and 'time' are subjective 'forms' of the mind, given prior to all experience. The findings of psychology are definitely opposed to this claim. Sensory experience contributes its share to our perception of 'space' and 'time,' as experimental psychology has definitely established. We acquire our knowledge of space and time from a perception of objects which are larger or smaller and which are at rest or in motion. Persons suffering from a congenital cataract have no antecedent knowledge of visual space; after a successful operation, they must acquire knowledge of space through *experience* and *perception*. If the subjective mental form of 'space' were, as Kant claims, a necessary condition for perception, making the perception of phenomena possible, then there seems to be no valid reason why the mind cannot impose the form of 'visual space upon the incoming impressions, even though a person be congenitally blind. The evidence, however, points clearly to the fact that the knowledge of space on the part of the mind is conditioned by the perception of the objects, and not that the perception of space is conditioned by some *a priori form* present in the mind antecedent to experience. But if 'space'

is an attribute of bodies, then so is 'time,' because both are on a par in this respect.

Fourth, Kant's theory is contrary to the fundamental principles of the *physical sciences*. Kant evolved his theory for the expressed purpose of revindicating scientific knowledge and freeing it from the bane of Hume's skepticism. He failed. Science treats of the *physical objects* of the extra-mental world and not of mental constructions; Kant's world, however, is a world of phenomena, and these phenomena are mental constructions which give us no insight whatever into the nature and reality of things as they are in themselves. According to Kant's conclusions, the physical, noumenal world is unknown and unknowable. Science is convinced that it contacts and knows *real things* outside the mind. Science is based on the *objective validity* of the Principle of Cause and Effect operating between physical objects and physical agencies; according to Kant, this principle is an empty *a priori* form merely regulating our judgments and applying only to phenomena. The *laws* which science establishes are considered by scientists to be real laws operating in physical bodies independent of our thinking; according to Kant, these laws merely relate to phenomena within the mind and not to nature at all. Kant states: "It sounds no doubt very strange and absurd that nature should have to conform to our subjective ground of apperception, nay, be dependent on it, with respect to her laws. But if we consider that what we call nature is nothing but a whole ['Inbegriff'] of phenomena, not a thing by itself, we shall no longer be surprised."¹ We are indeed surprised that Kant would accept this conclusion of this theory rather

than see therein the utter fallaciousness of the theory itself which could consistently lead to such a 'very strange and absurd' conclusion. That such a conclusion destroys the validity of science in its very foundations, must be obvious.

Fifth, Kant's theory destroys the foundations of *all intellectual knowledge*. Ideas and judgments are supposed to reflect and represent reality; they are supposed to tell us 'what things are.' Truth and error reside in the judgment. We have shown that in forming judgments we first understand the contents of ideas and then have an intellectual insight into the relation existing between the subject-idea and the predicate-idea. According to Kant, we do not make judgments because we perceive the objective relation of the subject-idea and the predicate-idea, but because a blind, subjectively necessitating law of our mental constitution draws certain sense-intuitions under certain intellectually empty categories prior to our thinking, and we do not know why these particular categories, rather than others, were imposed by the mind on these sense-intuitions. Our 'knowledge' is as blind as the law that produces it. Intellectual knowledge is thus utterly valueless, because it gives us no insight into the nature of the reality our ideas and judgments are supposed to represent.

Kant, in accepting Descartes' ultra-dualistic separation of body and mind, was forced to consider the mind as the sole contributing factor in the formation of universal and necessary ideas, judgments, and inferences. Everything is purely subjective. Subjectivism is the inevitable conclusion of any theory which overlooks the facts that man is an *integral psychophysical organism*.

The theories of innate ideas or mental forms are thus seen to be false, based on false assumptions.

Locke's Empiricism

Descartes' ultra-dualism of body and mind proved to be a fateful legacy for philosophic thought. His interpretation of the mind or soul, being ultra-spiritualistic, led to extreme idealism. His interpretation of the body, being ultra-mechanistic, led to empiricism, sensationalism, associationism, and materialism.

John Locke (1632—1704) followed in the footsteps of Hobbes (1588—1679), who was a sensationalist. Locke strenuously opposed Descartes' doctrine of innate ideas. In the beginning, he says, the mind is devoid of ideas, a 'blank sheet.' All knowledge has its origin in *experience*, in sense-perception. Experience is twofold, *sensation* (perception of external phenomena) and *reflection* (perception of the operations of the mind itself). From both sources we obtain 'ideas.'

Locke's philosophy centers in his theory of the ideas. Here is his understanding of an *idea*: "It being that term which, I think, serves best to stand for whatever is the object of the understanding when a man thinks, I have used it to express whatever is meant by *phantasm*, *notion*, *species*, or whatever it is which the mind can be employed about in thinking."² In this superficial definition Locke unfortunately lumps together as 'ideas' things which might conceivably be radically different in nature, namely, "phantasm, notion, species, or whatever it is which the

mind can be employed about in thinking.” By thus arbitrarily blurring the nature of the ‘idea’ so as to include the images of sense-perception (‘phantasm, species’), he laid the foundation for *sensism*, in which all ‘thinking’ is nothing but a form of ‘sensation.’ Descartes placed all sense-perception in the spiritual mind, thus identifying sense-perception with spiritual activity; Locke here does the reverse, by reducing ideas, at least in part, to the level of sense-perception.

This confusion of ideas and images is present in all his philosophy. He does not hesitate to assert that the Creator can make *matter think*: “I see no contradiction in it that the first eternal thinking Being should, if he pleased, give to certain systems of created senseless matter, put together, as he thinks fit, some degrees of sense, perception and thought.”³

Criticism. For one thing, Locke simply assumes without proof that ‘ideas’ and ‘images’ are identical. This identification of ideas and images wipes out the distinction between sensory and intellectual knowledge simply by *definition*. Again, according to his definition of the ‘idea’ the *idea* is the *object of our understanding*, instead of the *reality of things* being the object of our intellectual knowledge. All we can know, then, are ‘ideas,’ internal states of the mind; in that case, however, we can acquire no knowledge of the material world as it is in itself. If carried out to its logical conclusion, such a theory must inevitably end in subjective idealism. Furthermore, his confusion of ‘ideas’ and ‘images’ led him to the curious conclusion that God can make *matter think*. The empiricism of Locke made

him reduce 'thinking' to a property of matter, because he could not bridge the ultra-dualism of Descartes. But God, as T. V. Moore rightly observes, can no more make nonliving matter think than He can make a square circle. Only on the supposition that man is an integral organism, consisting of body and mind, is it possible to explain how sensations can give rise to images, and images to ideas through the process of abstraction. Finally, since all ideas originate either from sensation or from reflection on mental activities, Locke can give no proper explanation of ideas such as 'God,' 'soul,' 'good,' 'evil,' 'spirituality,' and a host of similar important ideas. We simply do not *experience* such realities in any form. Such ideas, then, should not be present in the intellect at all; they are, however, present and must be accounted for, though not according to the principles of Locke's empiricism.

Locke's empiricism was developed into a complete system of sensism by Condillac (1715—1780) who reduced the entire contents of the mind to 'transformed sensations.' Another offshoot of the empiricism of Locke is the *positivism* of Comte (1798—1857) who maintained that all knowledge is illusory except the 'positive' science of phenomena derived from sensation.

Sensationalism and Associationism

David Hume (1711—1776), accepting the fundamental tenets of Locke's empiricism, was more consistent than Locke and developed a thoroughgoing system of *sensationalism*.

According to Hume, the total content of the mind consists of *perceptions*. Perceptions are of two kinds: 'impressions' and 'ideas' or 'thoughts.' impressions are those perceptions which are more lively and forceful, and they include sensations and emotions. The faint images of these impressions Hume terms *ideas or thoughts*. Impressions (sensations and emotions) are experienced; ideas or thoughts (faint images of sensations and emotions) are revived in imagination and memory. 'Perceptions' thus form the total contents of our mental states, and they are *all we can know*. We can know nothing of objects or the qualities of objects. Even when we think we perceive our own body and its members, we perceive nothing but "certain impressions which enter by the senses." There is no such thing as a 'substance.' The mind is nothing but "a heap or collection of different perceptions united together by certain relations, and supposed, though falsely, to be endowed with simplicity and identity."⁴ Nothing is left, then, for knowledge but *phenomena*, subjective mental states, perceptions. As for the *cause* of the impressions which arise from the senses, Hume professes complete ignorance.

Relative to *universal ideas*, Hume maintains that we find a resemblance between objects and apply the same name to them; then, after a 'custom' of this kind has been established, the name revives the 'idea,' and the imagination conceives the object represented by the 'idea.'

A prominent part of Hume's philosophy is his theory of *associationism*. We speak, for example, of the Principle of Causality, and consider it to be a universally and necessarily valid axiom that 'Every effect must have a cause.' Hume

claims that this axiom is derived from experience. What we perceive is an *invariable sequence of events*: one thing invariably follows an antecedent event, and from this sequence we conclude that the antecedent event 'causes' the one that follows as an 'effect.' We do not perceive anything like the 'production' of one thing by another. From his phenomenalistic, sensationalistic standpoint, Hume could not admit real 'causation.' Whenever we observe one event to occur, we feel the mental compulsion to assert that the other will follow. But whence the mental compulsion to conjoin just these two events as cause and 'effect'? Hume gives as the reason that "the mind is *carried by habit*, upon the appearance of one event, to expect its usual attendant and to believe that it will exist."⁵ In other words, it is the *association of ideas* which compels us to formulate necessary and universal judgments, axioms, and principles. Such judgments, axioms, and principles have *no objective value*, but are mere associations of impressions derived from the succession of phenomena. As for the mental mechanism of association, it finds its explanation in the Laws of Association.

Criticism. First, Hume's explanation of *ideas* as *faint images* of sense-impressions is totally inadequate. Since both are of a sensory character, they are concrete and individualized. Our ideas, however, are abstract and universal. There is, as we have shown, a radical difference between 'sensations' and 'images' on the one hand and 'intellectual ideas' on the other. To ignore or deny these differences is a serious error.

Second, Hume's explanation of *universal ideas* is totally inadequate. The process of forming universal ideas is not at all the way Hume pictures it. We acquire them by a process of abstraction, taking the objective features common to a number of individuals and then generalizing the resultant idea so that it applies to the whole class and to every member of the class. It is not a question of merely labeling objects with a common name. Intellectual insight into the nature of these objective features, not 'custom' or habit, enables us to group them together into a class.

Third, Hume's explanation of the origin and nature of the necessarily and universally true *axioms and principles*, such as the Principle of Causality and the Principle of Contradiction, is totally inadequate. He explains their necessity and universality through *association*. Now, the laws of association are purely subjective laws with a purely subjective result. Consequently, the 'necessity' which we experience relative to the logical connection between subject and predicate in these principles would not be due to anything coming from the reality represented in these judgments, but solely to the *associative force* existing in the mind. It is a subjective and psychological, not an objective and *ontological*, necessity. The mind does not judge these principles to be true because it sees they cannot be otherwise; it *cannot see* them to be otherwise because the mind in its present constitution must judge them to be true. So far as objective reality is concerned, $2 + 2$ might equal 3 or 5 or any other number; and there might be a cause without an effect, or an effect without a cause. If Hume's contention were correct, that our observation of 'invariable

sequence' is the reason for assuming an antecedent event to be the 'cause' of the subsequent event, then we should perforce experience the same psychological necessity of judgment *in all cases* where we notice an invariable sequence in successive events. Experience, however, contradicts this view. For instance, day follows night in an invariable sequence; but no body would dream of asserting that the night is the 'cause' of the day. In an automobile factory one car follows the other on the belt line in invariable sequence; but this association does not compel us to think that the preceding car is the 'cause' of the one following. Reversely, when an explosion occurs but once in our experience, we search for the 'cause' of this 'effect' and are convinced there must be a cause present; here, however, there can be no question of an 'invariable sequence' of events.

Fourth, Hume's theory, if accepted as true, must *destroy all scientific knowledge*. The very foundation of science lies in the Principles of Contradiction, Sufficient Reason, and Causality. If these principles are valid only for our mind and do not apply with inviolable necessity to physical objects in nature, the scientist has no means of knowing whether his conclusions are objectively valid. His knowledge is nothing but a *purely mental construction* which may or may not agree with extra-mental reality. But science treats of physical systems and their operations, not of mental constructions. Since, according to Hume, we can know nothing but our internal states of consciousness, we could never discover whether the external world and other minds

exist at all; driven to its logical conclusions, such a theory can end only in solipsism or in skepticism.

Fifth, Hume's *Laws of Association are valid*, of course, in themselves; they were known and accepted, long before his time, by Aristotle and the Schoolmen. Hume, however, makes an illogical and illegitimate use of them, viewed from the standpoint of his own theory. According to Hume, the *total content* of the mind consists of *perceptions* (impressions and 'ideas' or images). Now, the Laws of Association, considered in themselves, are *not perceptions*, whether impressions or their images ('ideas'). The Laws of Association control, *regulate*, and link together these ideas; they are, therefore, over and above the ideas and distinct from them. According to Hume's own principles, then, they do not, and in fact cannot, belong to the content of the mind at all. Yet they are there.

Sixth, according to Hume, the *mind is its content*. In this view, there is no abiding mind or Ego in which impressions and ideas reside; all we have are perceptions (impressions and ideas) in a continuous flow; there is no mind or Ego distinct from these perceptions. Hume is very emphatic on this point. Theoretically, he denies the existence of 'mind' or 'Ego'; practically, he cannot, and actually does not, get along without a 'mind' or 'Ego.' He speaks continually of 'the mind,' 'we' and 'I,' and such terminology is inconsistent, to say the least. As a matter of fact, a 'mind' or 'Ego' is indispensable and *necessary to his theory*, notwithstanding his denial of their existence. The reason is plain. The Laws of Association, so basic to his theory, are merely the laws *according to which* ideas are conjoined;

they themselves do not do the conjoining. Something, then, must be present which applies the Laws of Association to the ideas and *associates* them; without this 'something' these laws would be inoperative. Hume cannot explain the operation of these laws without a 'mind' or 'Ego' to operate them. Thinking demands a thinker, just as motion demands a moving object.

Seventh. Hume's theory is *atomistic*. It cannot be otherwise. Every sensation, emotion, and idea is a single item of consciousness, similar to an atom in nature. Each, as Hume expressed it, is a 'distinct existence.' Each is a solitary reality, having only an instantaneous existence; it comes, abides for a moment, and is irrevocably gone. No two items exist simultaneously; one succeeds the other in the flow of conscious events. And the important point is this: there is no 'mind' or 'Ego,' distinct in being from these experiences, which would be an abiding reality behind them, capable of experiencing them. Since each item of experience has but a momentary, isolated, and solitary existence, there is nothing present which could hold them together, *compare* them, and *synthesize* them. All we can have is an unrelated, kaleidoscopic succession of items. The formation of *general ideas, judgments, and inferences* should thus be utterly impossible, since there is no 'mind' or 'Ego' present to observe whatever *relations* might exist between ideas or things. But we have such general ideas, judgments, and inferences. Hume's theory, therefore, is utterly false.

Hume himself gave expression to the *dilemma* of the position in which he had placed himself. He said: "There are

two principles which I cannot render consistent; nor is it in my power to renounce either of them, viz., *that all our distinct perceptions are distinct existences, and that the mind never perceives any real connection among distinct existences*. Did our perceptions either inhere in something simple and individual, or did the mind perceive some real connection among them, there would be no difficulty in the case.”⁶ This statement is a frank confession that a ‘thinking mind or Ego’ is necessary to explain our thought processes. But Hume would not accept this conclusion and thereby pronounced the complete failure of his theory of knowledge. He became a skeptic.

Hume exerted a tremendous influence on English and American philosophy, an influence which is felt even to this day.

Imageless Thought

Sensationalism and associationism dominated psychology for a long time. Each philosopher treating of psychological subjects introspected his own personal mind and its operations and then proceeded to make dogmatic pronouncements concerning them. Such was the method employed by Locke, Berkeley, Hume, J. Mill, Bain, Spencer, and other prominent English writers. Experimental methods were not used, for the simple reason that experimental psychology was not as yet in existence. The application of experimental methods to psychology did much to remove personal speculation and place psychology on a sounder factual basis. The first consistent experimental

investigations into the nature of the thought processes began around the turn of this century.

A. Binet (1903) tested the sensationalist theory, to which he subscribed, through experiments on his two young daughters, expecting to find that thoughts were nothing but images. He came to the definite, and to him amazing, conclusion that 'naked thoughts' existed in the mind and that 'images' are extraneous to real 'thinking.'

More extended and systematic investigations along these lines were made by the psychologists of the *Würzburg School*, prominent among whom were Oswald Külpe (1862—1915), K. Marbe, and K. Bühler. Using the method of proposing questions and problems to their observers, they attempted to find out just what takes place in the mind in the formation of ideas, judgments, and inferences. In this manner they hoped to settle the question whether *ideas are identical with images* or whether *thinking transcends imaging*.

Sifting the evidence obtained from the subjects concerning their experiences, it was found that images of various types usually were present in the thought processes. The evidence, however, revealed a clear distinction between *knowing* and *sensing* or *imaging*. 'Understanding' and 'insight' were something totally different from the images. 'Meaning' was something over and above the images flitting through the mind during the process of thinking. In many instances, the subjects claimed, ideas were present, but no perceptible image; they experienced *imageless thought*. In any case, whenever images were present together with ideas, the images were

recognized as merely accompanying the ideas, as adventitious to thoughts, and not as constitutive of, or essential to, the meanings. Usually, too, the images were soon forgotten, while the meanings, the ideas, the knowledge remained and were remembered. The psychologists of the Würzburg School soon learned that a distinction had to be made between the 'picturable and unpicturable contents of conscious processes' (*anschauliche und unanschauliche Bewusstseinsinhalte*). They mean that some contents of our mind can be 'pictured' or 'imaged,' such as a 'house' or 'horse,' while other contents cannot be 'pictured' or 'imaged,' such as a 'negation' or the 'will.' The latter are ideas. Ideas, therefore, are not images, even when images accompany ideas. From these and similar facts brought to light in the psychological laboratories of the Würzburg School, Bühler drew the general conclusion: "What enters into consciousness so sporadically, so very accidentally as our images, cannot be looked upon as the well-knitted, continuous content of our thinking."⁷

The main point about all these experiments is not whether thoughts can occur without images, but whether thoughts are identical with images. These psychologists have adduced considerable evidence in favor of *imageless thought*; but the evidence is not conclusive, and further experiments will have to be made. They have, however, definitely established the fact that *ideas are not images*. Sensationalism has thus been disproved on experimental grounds.

Later experiments, made by R. S. Woodworth, G. H. Betts, T. V. Moore, R. Clark, A. Willwoll, J. Lindworsky, and

others, have confirmed the findings of the Würzburg School.

In general, the Würzburg School agrees with the teachings and principles of the traditional aristotelian-scholastic philosophy concerning abstraction, universal ideas, judgments and inferences, as expounded in the foregoing chapter. Experimental methods thus furnish positive proof that intellection is a supra-sensuous process.

E. B. Titchener (1867—1927), the noted head of the department of psychology at Cornell University, disputed the findings of the Würzburg School. On the strength of the experimental studies conducted under his guidance, he claimed that his observers always thought in images. Titchener, a sensationalist himself, contended that all thought processes can be reduced to ‘sensations,’ so that the ‘sensation’ is the ‘structural unit or element’ of everything occurring in consciousness; his theory is therefore sometimes referred to as *structuralism*, but it is really nothing more than a form of sensationalism.

Titchener denies that there are ‘unpicturable meanings’ of ideas. He himself, he says, always imaged meanings, even ‘meaning’ itself. Here is his description of ‘meaning’ as he images it: “I see meaning as the blue-grey tip of a kind of scoop, which has a bit of yellow above it (probably a part of the handle), and which is just digging into a dark mass of what appears to be plastic material.” One of his subjects saw meaning’ as the “unrolling of a white scroll”; another saw it as “a horizontal line, with two short verticals at a little distance from the two ends.”⁸ Here we have, if images are really ideas, three distinct individual meanings of

‘meaning’! These irrelevant images are not what we *understand* by ‘meaning’; ‘meaning,’ as any dictionary will disclose, is that which is signified by an idea or word and which is expressed in a definition, the comprehension or intention of a word or idea, and that is something very different from the images mentioned above.

The egregious fallacy of the Cornell method consisted in the presupposition that ideas and images are identical; the subjects were instructed to *look for images* in their thought processes. They neglected ‘ideas’ in the search for ‘images.’ Thus, Dr. Geissler was told to look for the meaning of the sentence ‘Did you see him kill the man?’ He reported that he had “No meaning all the way through.”⁹ By ‘meaning’ he meant ‘image.’ He had no ‘image,’ but he certainly *understood the sense* of the sentence; any child would understand that. In other words, he had an ‘idea’ but no ‘image.’ If anything, such a report bears out the main contention of the Würzburg School that *images are only accessory products* of the thinking process.

It was the abuse of the introspective experimental method of the Cornell School that called forth a denunciation from Watson and prepared the way for behaviorism.

Gestaltism

Besides the Würzburg School of experimental psychology, the psychology of *Gestalt or configuration* has risen in opposition to sensationalism. There are really two Schools of Gestalt. The Old School originated with *F. Brentano*, in

1874. He had been trained in scholastic philosophy, and he stressed the supra-sensuous character of thought. But it was the work of two of his students, *A. Meinong* and *C. von Ehrenfels*, who developed the ideas of Brentano into what is now known as the Psychology of Gestalt. In particular, it was von Ehrenfels (1890) who showed that 'configurational qualities' exist in many types of perceptions, so that we apprehend these complex perceptions as 'wholes' rather than as mere 'aggregates' of sensory impressions. Meinong came to the conclusion that in Gestalt, in many instances, meanings are involved which are more than the resultants of sensations and cannot be explained on the basis of sensation, because they are altogether *objects of a higher order*, namely, conceptual or intellectual. This view was, of course, diametrically opposed to the 'atomistic' sensationalism prevalent in psychology at the time and practically amounted to a return to scholastic psychology, because over and above the sensory data of perception there must be the interpretative thought process as the configuring principle. Since Meinong taught at Gratz, the Old School of Gestalt psychology is often referred to as the *School of Gratz*.

The *New School* is called the *School of Berlin*, because *M. Wertheimer* and *W. Koehler*, who, together with *K. Koffka*, were mainly responsible for the new development of configurational psychology, taught at Berlin. These authors extended and deepened the researches begun by their predecessors of the Old School, especially by applying the experimental methods of modern psychology to the problem of configuration in perception. The New School

began with an essay by Wertheimer on the perception of movement, written in 1912. Today Gestaltism is receiving considerable attention and has a large following.

The final conclusion of the studies of the Gestaltists can be condensed into the statement: Perception is not the mere sum of individual 'atomistic' sensations, but the resultant of the total sensory impression.

Unfortunately, the School of Berlin opposed the intellectualism of the parent School of Gratz and attempts to explain all configuration on the basis of sensory perception, ignoring entirely the *intellectual interpretation* of the cognitive processes. The pathology of perception, as noted in cases of cortical blindness and in persons operated on for cataract (see above, Chap. 7), reveals the fact that configurations may be 'apprehended' and yet not 'understood.' Over and above perception, therefore, we have supra-sensuous thought processes dealing with intellectual meanings. The School of Berlin is still caught in the web of *sensationalism*, although it stands in opposition to the old-style sensationalism of Hume and his followers. Nevertheless, it is a step in the right direction.

For three centuries the ill-fated ultra-dualism of Descartes has played havoc in the minds of philosophers. System after system has been devised, only to be found in the end to be inadequate. Slowly but steadily experimental psychology is forcing philosophers and psychologists into recognizing that man is not pure spirit nor pure matter, but a unitary being composed of a material body and of a sentient, intellectual mind, an *integral organism*. We will next consider the peripatetic theory.

Summary of Chapter XIII

There are three main classes of theories which attempt to explain the *origin of ideas*: the theory of innate ideas; the empiricist or sensationalist theory; and the peripatetic theory.

1. *Plato's Ultra-Realism*. In order to account for the unchangeable and universal character of universal ideas and scientific knowledge, Plato postulated the existence of a supra-mundane *world of Ideas* or pure essences. Man must have lived in this world in a former existence, contemplating the Ideas, and he recalls them in the present existence. Universal ideas are thus innate.

Plato's theory presupposes that the relation between body and soul is *unnatural* and *extrinsic*; this relation however is natural and essential. We should be able to *remember* our former existence; but we do not.

2. *Descartes' Ultra-Spiritualism*. Descartes taught that body and soul are two intrinsically independent substances. The body is a mere machine; the intellect is the exclusive cause of all knowledge. Ideas are *potentially* innate and subsequently become actual.

Descartes overlooked the fact that man is a psycho—physiological *organism*. Sense organs are *vital instruments* of knowledge, and ideas can thus be formed through a process of abstraction from sense images.

3. *The Monadism of Leibnitz*. Every being consists of monads, all of which are without contact with other monads

but have 'power of representation.' All ideas are innate as 'natural virtualities.'

Monadism is a gratuitous theory. If the theory were correct, there would be no need of sense organs and a nervous system. The theory leads to *solipsism*.

4. *Ontologism*. The theory claims that man intuits *God* and the *divine Ideas* in their relation to creatures and knows the objects of the world thereby.

This theory is contradicted by consciousness. If we beheld the divine Ideas, we would behold God's essence; but our knowledge of God is *indirect, analogous*, and by *negation*.

5. *Kant's Transcendental Criticism*. There is a noumenal world of things-in-themselves; of this world we can know nothing. The noumena affect the senses. Sense impressions are cast into the molds of *two innate a priori mental forms*, 'space' and 'time,' giving us phenomena. In the intellectual field there are twelve *innate a priori* judgment forms, the 'categories.' Reasoning is government by three *innate a priori* forms, the ideas of 'soul,' 'matter,' and 'God.' None of these 'forms' have objective value, but they are the conditions which make knowledge possible; they are present in the mind antecedent to all experience and therefore innate. The necessity and universality of ideas, judgments, and inferences are derived from these innate forms.

The theory is false. It makes knowledge *illusory*. We can know nothing of the external noumenal world; yet Kant knows that it is a 'chaotic manifold.' The theory is contrary to the science of *psychology* which shows that sensory

experience contributes to the perception of 'space' and 'time.' It is contrary to *physical science* which treats of a real, not a merely phenomenal, world. It destroys *intellectual knowledge*, since it bases knowledge on the blind compulsion of mental 'forms' instead of 'insight.'

6. *Locke's Empiricism.* Locke considers the *object* of the intellect to be the *idea*; and he confuses the idea with the phantasm or image. He contends that *matter can think*.

The object of the intellect is *reality*, not the idea. By confusing 'idea' and 'image,' he wipes out the distinction between intellectual and sensory knowledge. 'Thinking matter is as impossible as a 'square circle.' Locke cannot explain the origin of supra-sensuous objects, such as 'God,' 'good,' etc., because we do not experience them.

7. *Sensationalism and Associationism.* According to Hume, the total content of the mind consists of *perceptions*, namely, 'impressions' and 'ideas'; the latter are faint images of impressions. All we can know are phenomena. The universality and necessity of judgments rest on *association*: because we observe an invariable sequence of events, we judge the antecedent events to be the 'cause' of the subsequent events.

'Ideas' are not 'faint images' of sense-impressions: ideas are abstract and *universal*. Universal ideas are the result of abstraction. Axioms and principles are the result of intellectual *insight*, not of association. His sensationalism destroys all scientific knowledge, because all knowledge would be but a mental construction. The Laws of Association are *not perceptions*; they control and regulate perceptions. He eliminates the 'mind' or 'Ego,' but the Laws

of Association demand something that *applies* them. Hume's theory is *atomistic* and therefore excludes the possibility of *synthesis*.

8. *Imageless Thought*. The experimental methods of the Würzburg School disproved the identity of 'images' and 'ideas.'

Images usually accompany ideas; but they are *accidental* and *accessory*, not essential to ideas. Many thoughts, some of these psychologists insist, are 'imageless.'

Titchener defends sensationalism. His method was faulty, because his subjects were instructed to look only for images in their processes.

9. *Gestaltism*. The School of Gratz arrived at the conclusion that 'meanings' cannot be explained by sensation, but are objects of a *higher order*. The School of Berlin explains configuration or Gestalt on the basis of sensory perception, ignoring the *intellectual interpretation* of the cognitive processes. The School of Berlin, although it disproves the 'atomism' of Hume, is sensationalistic.

What most of these systems overlook is the fact that man is an *integral organism* consisting of body and mind; hence their errors in explaining the origin of ideas.

Chapter 14

ARISTOTELIAN IDEOGENY

THE FORMATION OR GENESIS OF IDEAS IS TERMED *IDEOGENY*. There is one theory which offers a far better explanation than any of the theories discussed in the preceding chapter. It is in fundamental agreement with all the data brought to light by modern experimental methods, though this theory itself was not developed and formulated on the basis of experimental method but on the basis of wide observation, acute introspection, and logical deduction.

The theory dates back to *Aristotle* (384—322 B.C.), perhaps the greatest philosophical genius of all times. Because of his custom of strolling about while discussing problems with his pupils, the followers of Aristotle were named ‘peripatetics,’ and his teachings ‘peripateticism.’ His theory of the origin or genesis of ideas in the human intellect is therefore often referred to as *aristotelian or peripatetic ideogeny*.

Aristotle’s philosophy was adopted by the Schoolmen or scholastics of the Middle Ages, and they developed his doctrines along many lines. The combination is usually styled *aristotelian-scholastic philosophy*. To St. Thomas Aquinas (1225—1274), the pre-eminent medieval

philosopher, must go the credit of having introduced Aristotle's complete philosophy to the Western World and then developing it into a grand Christian world-synthesis. Due to his epoch-making work, history has linked his name to that of Aristotle and characterizes this rejuvenated peripateticism as *aristotelian-thomistic philosophy*.

It is the aristotelian-scholastic theory of ideogeny which will be outlined in this chapter.

Intellect and Thing

That man's ideas contain a true knowledge of the external world, is the conviction of all mankind; it is also the conviction of scientists and psychologists who are not prejudiced by philosophical theories. The epistemologist¹ has the duty to prove that this conviction is rationally justified. The problem before us consists in giving a satisfactory account of the various stages which intervene between the things of the world as they are in themselves and the ideas representing them as formed by the intellect.

Now, it is an axiom of aristotelian-scholastic psychology that ***nothing is in the intellect which was not first (in some manner) in the senses*** (*Nihil est in intellectu quod non fuerit prius in sensu*). The axiom is in perfect accord with everyday experience and with experimental psychology.

We have no innate ideas. That was shown in the discussion of the various theories of innatism. As far back as our memory reaches, we are conscious of *three successive states of mind* concerning knowledge. At first we are in

ignorance relative to a subject matter (for example, history, geometry, language, etc.), so that we are in a state of 'potential' knowledge only. Then, we acquire a knowledge of a subject matter by learning, so that at the time we possess 'actual' knowledge of it. Finally, this actual knowledge recedes into the storehouse of memory, remaining there in a latent condition but capable of being recalled; this latent knowledge is called 'habitual.' The study of the knowledge process of infants and children confirms this view; they show no signs of ready-made innate ideas, but acquire their ideas and knowledge as just indicated. By a process of legitimate induction, therefore, we must conclude that the intellect of man is *originally devoid of ideas, a tabula rasa* or 'blank slate,' and it must acquire its knowledge 'from without.' Our ideas, therefore, have their *source outside the intellect*; they are acquired and formed, not innate and given.

Knowledge implies three things: the thing that becomes known; the subject or intellect that knows the thing; and the process whereby the thing becomes known to the intellect. There must be a union between the knowing subject and the known thing, so that the thing is made present to the subject.

The intellect alone is not sufficient for cognition. Of itself, the intellect is indifferent as to what sorts of things it knows; it is not determined by its own constitution to know just this and that definite thing or this thing rather than that thing. A person blind or deaf from birth through physical disability has no knowledge of color or sound. Somehow, then, the *physical things* must be brought before

the intellect. And this union between thing and intellect must be such that the knowledge thus acquired corresponds to reality; otherwise this knowledge would be false and useless.

The union between intellect and thing can conceivably take place in one of two ways. It might be a *physical union*; in that case the thing itself in its concrete entity would be taken into the entity of the intellect. Or, it might be a union by representation or resemblance; in that case the physical thing itself would remain outside the intellect, but some sort of representation, resembling the physical thing and thereby making it known, would be produced in the intellect. It is obvious, that things do not enter or contact the intellect in their physical entity and existence. When I acquire knowledge of a person or house, that person or house does not travel to me, enter physically into my intellect, and thereby become known to me; nor does my intellect travel to the person or house, envelop it, and thereby come to know it. Intellect and thing remain physically apart and retain their separate existence. Hence, the union between mind and object must be by representation or resemblance.

This representation or resemblance of the thing must be one either *of nature or of image*. The representation or resemblance in the intellect is one of 'nature,' if the thing and its representation in the intellect would exist in the same natural conditions. For example, in such a supposition a windowpane as existing in the world and its representation in the intellect would both be made of glass; if the thing is made of gold or brass or wood, its

representation in the intellect would also have to be made of gold or brass or wood. The representation or resemblance in the intellect is one of 'image,' if it is a likeness of the thing, but differs from the thing in its natural conditions or materials. For example, a photograph or painting of a person is a representation, resemblance, or likeness, but it does not consist of the same materials nor does it exist in the same natural conditions as the person represented. It is obvious, of course, that our representation of a brick wall is not made of brick, and our representation of a windowpane is not made of glass. Nor is such an identical representation required. A photographic image can give us accurate knowledge of the appearance of a person, although the material or nature of the represented person and the representing likeness or image is totally different. A motion picture resembles the persons and scenes it depicts, and we acquire thereby considerable knowledge of them, even though the picture is devoid of the conditions and materials present in the original things. Hence, the representation, resemblance, or likeness present in the knowledge process of the intellect must be one of image. A *cognitional image* suffices and is necessary, in order to make the thing known to the intellect.

The external thing, then, becomes known to the intellect by means of a cognitional image. In as much, however, as the intellect, at first, is in a state of potential knowledge, this cognitional image must in some manner be derived *from the thing*. By what process is this cognitional image made?

Role of the External Senses

We know the answer from the sciences of physics and physiology. Things do not produce cognitional images in the intellect directly. *Forms of energy* (light-waves, air waves, heat, electricity, etc.) issue from the things and impinge on certain nerve terminals situated in certain structures of the human body; these structures and their nerves (sense organs) are specifically designed to act as receptors for these energy influences. The physical stimuli, proceeding from the things, activate the external senses by arousing a nerve impulse which travels along the afferent nerve fibers to receptive centers of the cortex of the brain. The response of this neurological mechanism is a *sensation* of color, sound, flavor, odor, pain, warmth, etc.

The response of sensation to the energy stimuli is not purely passive; it is an active vital process on the part of the sentient subject. The stimuli themselves are not vital and are not sensations; they are physical causes which stimulate the sentient subject to *actively produce within itself the vital response of sensation*. Just what kind of sensation is produced by the sensing subject within itself depends on the type of stimuli proceeding from the object. Sensation, therefore, is not a purely subjective product of the sensing subject. The sensing subject is determined in its sensory response partly by its own vital nature and partly by the character of the incoming stimuli. Sensation is thus seen to be the product of a double factor: one *objective*, the physical stimuli issuing from the external thing; and one

subjective, the vital power of the sensing subject to respond to the particular stimuli with particular kinds of sensations.

That such a process actually occurs, should be clear from what has been said about the sensations in previous chapters. There it was shown that sensation is not a mechanical process in which the sensing subject participates in a purely passive fashion. On the contrary, the sensing subject responds actively by producing within itself a vital modification. This *vital modification*, the sensation, corresponds to the nature of the stimuli activating the senses, but it also differs from them in many respects. Since the stimuli reveal the thing to the sensing subject, this vital modification or sensation is a *cognitional image* of the object, but only an 'image' in its rudimentary stage; it is the first step in making the thing known to the intellect.

Even in this rudimentary stage, it will be noted, the cognitional image is not *physical*, but psychical. It does not consist of material stuff, such as exists in the thing which it represents.

The image is of the nature of the sensing subject rather than of the sensed thing; it is a mental image, not a physical copy. As the seal leaves upon the wax a likeness of itself without giving to it any of its material, so the material things are instrumental in impressing upon the senses their image without the gross conditions of matter.

In order to understand the nature of this cognitional image, even in its rudimentary stage, the body of man must be considered, not as an aggregate of inanimate chemical elements and compounds, but as a *vitalized organism*. Sensations are 'vital' mental products, different from the

physical stimuli to which they are a response. The sensation of 'color,' for example, is something very different from the pattern of ether waves spread over the retina, and the sensation of 'sweet' is very different from the reaction of sugar with the chemical substances of the tongue. If sensations were the exclusive product of the sensing subject, we would have sensations, but no 'representation' or image' of the thing; and if the response were the product of a non-vital sense mechanism, we would have chemical and physical reactions, but no 'sensation.' But if man is an *integral organism*, we can understand how physical and chemical stimuli can affect the vitalized physical and chemical constituents of the senses and arouse in them a vital sensory response. And we can also understand how the sensing organism can respond to the causal action of the stimuli with sensations which are a rudimentary cognitional image capable of being elaborated eventually into a completed image of the thing.

Role of the Internal Senses

The rudimentary cognitional image of the thing, given in the sensations experienced by the sensing subject in response to the various types of stimuli issuing from the thing, is made into a completed cognitional image through the operation of the *internal senses*.

Sensations are in the nature of irreducible and isolated items of mental experience. They are like the single pieces of a jigsaw puzzle. Viewed separately and individually, the pieces are fragments of a picture; put together in their

proper order and position, they form a unified and complete picture (representation, image, likeness, similitude) of a thing or scene. If there were *no central or synthetic sense*, the sensations would remain in their isolated and fragmentary condition. But the central or synthetic sense makes the sensing subject aware of the various sense qualities (a color, a tone, an odor, a flavor, etc.) as occurring simultaneously, combines them, and refers them to some definite thing as a *perceptual whole*. It synthesizes the jigsaw pieces of sensations into a unified *phantasm* of the sensed thing. This phantasm is the total sensory impression or completed cognitional image of the thing furnishing the stimuli which arouse the sensations. The phantasm is the unitive bond between the sensing subject and the thing, making the thing known in a sensory manner.

An example. Before me there is an orange which I proceed to peel and eat. My sight has a sensation of yellowish color on a surface which has a spherical contour; my fingers have a sensation of the texture of the orange, partly rough and partly smooth, together with a sensation of spatial dimensions; my nostrils have the sensation of a fruity odor; as I munch the segments, my tongue has the sensation of sweetness; my mouth has the sensation of pressure and temperature. Each sensation is a separate item mediated by a separate sense; each single sense knows nothing of the sensation mediated by the other senses. If this were the entire story of our experiencing, we would have only a confused and confusing mass of isolated sensations. All these isolated sensations, however, are experienced simultaneously (or nearly simultaneously) by

the one sensing subject; they are combined into a *total sensory impression or phantasm* by the synthetic sense and referred as a 'perceptual whole' to the same thing, the 'orange.' This phantasm is the completed cognitional image presenting the thing to the sensing subject through the mediation of the synthetic sense in co-operation with the external senses.

In the terminology of aristotelian-scholastic psychology, the sensations are the *received or impressed sensible image (species sensibilis impressa)*, which arouses the synthetic sense into action by its presence. The synthetic sense responds to this sensory determinant,' as D. Card. Mercier styles the impressed sensible image, by forming the phantasm or completed sensory cognitional image of the object. The phantasm or completed sensory cognitional image, elaborated into a perceptual whole from the sensations by the synthetic sense, is the *formal or expressed sensible image (species sensibilis expressa)*. For brevity's sake, this completed sensory cognitional image representing the sensed thing is called phantasm. The phantasm, therefore, is formed by the synthetic sense while the thing is *present to the senses* and activates them through its stimuli. This phantasm truly *represents* the thing, because it manifests the qualities and attributes of the thing to the subject by means of the stimuli and of the sensations resulting therefrom.

It must be stressed again, that the phantasm (cognitional image) is a representation of the external thing, but it is a psychical or mental, not a physical or purely material, likeness. The senses perceive color, sound, bitterness,

hardness, etc., but the phantasm itself is not colored, sonorous, bitter, hard, etc. The phantasm is a vital modification of the knowing subject and as such partakes of the nature of the knowing subject. This fact is expressed in the axiom: *The known object is in the knower according to the nature of the knower (Cognitum est in cognoscente secundum modum cognoscentis)*.

Once the phantasm ('expressed sensible image') is formed by the synthetic sense, it is taken over by the *imagination* and stored away. The phantasm does not remain in the imagination precisely as a 'phantasm,' such as it was when formed by the synthetic sense, but as a 'trace,' or 'disposition.' Later on, this 'trace' or 'disposition' can be activated, so that the 'phantasm' or image' will be revived. In the absence of the original thing, therefore, the phantasm or image can be reproduced and contemplated; for cognitional purposes, the phantasm or image *takes the place of the original thing*, and the thing can be studied in its cognitional image as if the thing itself were again present. The thing itself may have been sensed for only a brief period of time, never to be actually sensed again, as when we travel once and only once through a city or country. The recalled image of the thing can be studied at leisure in a sort of vicarious sensory experience; the intellect thereby has a greater opportunity to form ideas of the thing.

Memory also plays its part in this psychological process. It is memory which dates and localizes past experiences and identifies a certain phantasm or image as representing some particular thing *sensed before* at a definite time and

place. It recognizes the object in its cognitional image, so that the intellectual ideas derived from this image are equivalent to ideas derived from the thing itself as represented in the phantasm of the synthetic sense made in the thing's own presence.

These, then, are the two preliminary stages in the total process of the formation of ideas: the genesis of the *rudimentary cognitional image* ('impressed sensible image') of the sensations, produced by the external senses and the cerebrum in response to physical stimuli proceeding from the thing; and the completed or *formal cognitional image* ('expressed sensible image') of the *phantasm*, made by the synthetic sense from the sensations and conserved by the imagination.

Agent Intellect

From the sensory field we pass to the intellectual field. Intellection begins where sensory experience ends.

Ideas are of a higher order than images; ideas are abstract and universal, while images are concrete and individualized. It follows that images cannot be the efficient cause of ideas, because there would be a disproportion between cause and effect. Just as the phantasm had to be formed by the synthetic sense through a sensory process in response to the stimuli in the sense organs, so the formation of ideas must proceed from the *intellect* through an *active intellectual process* in response to the phantasm or image. There are no innate ideas in the intellect, and there is nothing in the intellect which was not first

somehow in the senses; the intellect, therefore, must derive its ideas in some manner *from the senses*. How does the intellect do this?

According to the aristotelian-scholastic theory, the intellect forms its ideas by *turning its attention upon the content of the phantasm (se convertendo ad phantasmata)*. Most scholastics interpret the term 'phantasm,' used by Aristotle and St. Thomas in this connection, as meaning the revived phantasm or image of the *imagination*. Taken in this sense, ideas are not derived from the phantasm made by the synthetic sense in the presence of the stimulating thing. This view is probably erroneous. T. V. Moore,² after an analysis of pertinent passages of Aristotle and St. Thomas, arrives at the conclusion that both understood the term 'phantasm' in a *generic* sense, including the phantasm formed by the synthetic sense in the presence of the object and the revived image of the imagination in the absence of the object. Both types of images are 'phantasms,' and the intellect can form ideas by turning its attention to either one. After all, the *cognitional content* of both is *identical*. The image of the imagination is fashioned from the phantasm of the synthetic sense and is a replica of it. No valid reason can be assigned why the intellect should not be able to turn its attention to the original phantasm of the synthetic sense as well as to the derived image of the imagination; if the intellect can turn its attention to the latter, it must be able to turn its attention also to the former. After all, experience shows that we form ideas of objects while we actually perceive them, i.e., *while we have a percept of them* in the synthetic sense.

Ideas are formed, then, by the intellect in one of two ways: by turning its attention *either* to the phantasm of the *synthetic sense* in the actual perception of the thing or to the phantasm (image) of the imagination in the recalled impression of the absent thing. The result is, in general, the same, because the cognitional content of both types of phantasms is the same: both are a psychical likeness of the perceived thing. The *superiority* of the idea, relative to the phantasm, consists in this that the content of the idea represents the thing as divested of the *material conditions* proper to material things. The senses represent things in the concrete conditions of their individualizing material determinations (shape, size, color, etc.); the intellect, however, represents things as divested of these concrete conditions, by leaving the individualizing material determinations aside and concentrating its attention on the *essence* or '*whatness*' of the thing ('what they are,' instead of 'how they appear'). The intellect divests the representation of its concrete conditions, by the now familiar process of *abstraction*; thereby the 'sensible' becomes '*intelligible*' to the intellect. The 'essence,' or 'nature,' or 'whatness,' is said to be 'abstracted' from the phantasm by the intellect.

When it is said that the 'whatness' or the '*quiddity*' (Lat., *quid*, what; *quidditas*, whatness) is 'abstracted' from the phantasm, we must guard ourselves against placing too literal an interpretation on the term 'abstraction.' It does not mean that the intellect actually 'draws out' the phantasm from the synthetic sense or imagination, immaterializes the phantasm itself, and then takes it over as

an 'idea,' thereby converting the sensible image into an intelligible image. The phantasm remains in the synthetic sense or in the imagination as a sensory representation of the thing, unchanged and intact. The intellect, however, while contemplating the phantasm present in the synthetic sense or imagination, *actively generates within itself* an intellectual representation of the thing according to its essence or 'whatness (*quiddity*),' thereby making the thing *actually intelligible* or understandable for the intellect. Aristotelian-scholastic psychology speaks of this process as 'illuminating the phantasm' and 'abstracting the essence or nature from the phantasm.'

Since the idea is a supra-sensible (because 'abstract') representation of the thing, the abstractive process whereby the idea is formed must be a *supra-sensible process*, and the abstracting intellect must be a *supra-sensible power*. The phantasm, therefore, since it is but a sensory product, cannot make an impression on the supra-sensible intellect by being, as it were, projected on the intellect; for the same reason, the phantasm can neither be converted into an idea nor reside in the intellect. The intellect forms its idea of the thing during the contemplation of the phantasm by means of an naive interpretation of the content of the phantasm.

This interpretation of the content of the phantasm is possible, because the same knowing subject is consciously active in sensation and intellection and is consciously aware of the phantasm and its content as a sensory representation of the thing. Since the one who senses and the one who thinks is the same perceiving individual man, man is not

only aware of the phantasm but also is aware of what the phantasm represents and means; he *interprets* the phantasm as a representation of the thing and thereby knows *what the thing really is in itself*.

Now, this power or capability which actively *modifies itself so as to represent within itself in an abstract manner what is concretely represented in the phantasm*, is termed the *agent intellect*. Some call it the 'active intellect.' St. Thomas and the Schoolmen termed it *intellectus agens*; so the term 'agent intellect' seems preferable.

The agent intellect is a certain instinctive supra-sensory energy or power which acts spontaneously on the phantasm present in the synthetic sense or imagination and generates within itself an *intelligible cognitional image of the thing* represented by the phantasm.

The agent intellect is the principal efficient cause in the formation of this intelligible cognitional image. The phantasm presents the quiddity or essence of the thing, but this quiddity is concretized in material conditions and determinations. I behold, for example, a human being and make a phantasm of him in all his individualized concreteness of shape, color, size, sex, etc. The agent intellect unites its activity with that of the perceiving synthetic sense, drops all the concrete particulars, and abstracts from the phantasm those features which are essential to man as 'man.'

Without the sensory cognitional image of the phantasm the agent intellect can do nothing. When, however, the phantasm is present, the agent intellect naturally and instinctively goes over into its abstractive activity. The

product of this abstractive activity is the *vital determination of the intellect* to the act of understanding, to the *intellectual perception* of the quiddity of the thing represented in the phantasm. This 'vital determination' of the intellect is termed the received or impressed intelligible *cognitional image* (*species intelligibilis impressa*) or the 'impressed intelligible species.' The impressed intelligible species is still not the full and complete 'idea' of the thing, but the immediate preparation for the 'idea'; its relation to the full and complete 'idea' is the same as that of the 'sensations' to the full and complete 'phantasm' of the synthetic sense.

M. Maher characterizes the agent intellect as follows: "The intellectus agens [agent intellect] must be conceived as instinctive or blind; its 'abstractive' action is *productive* of intelligence, not formally intelligent itself. Its function is to *effect* the modification by which the act of intellectual consciousness is immediately awakened. It may be here asked if the action of the *intellectus agens* be *instinctive*, why does it issue into the precisely appropriate activity? Why does it *effect exactly the right modification* to represent the object of sensory impression when the latter cannot directly act upon it? The answer lies in the fact that *both senses and intellect have their source in the same individual soul*, which is so constituted that on the *stimulation of the former the latter sympathetically responds* by a higher reaction of its *own* — somewhat as the appetitive faculty, which conceived as such is blind, tends towards an object apprehended by a cognitive faculty as

good. In both cases it is the soul itself which acts through the faculty.”³

The Potential Intellect

The phantasm, then, is ‘potentially intelligible,’ because it contains the essential elements of the thing in a concrete form; it becomes ‘actually intelligible’ when the agent intellect grasps the essential elements through its abstractive activity. These essential elements must now be fashioned from a rudimentary cognitional image (impressed intelligible species) of the agent intellect into the *completed or formal cognitional image*, namely, into an ‘idea.’

The *power or capacity* of the intellect to *express the essence of the represented thing in an ‘idea’ or ‘concept’* is termed the *potential intellect (intellectus possibilis)*. The term ‘potential’ does not mean ‘inactive.’ It merely signifies that the intellect is ‘receptive’ of the vital determinant or modification (impressed intelligible species) received by it from the agent intellect, before it proceeds to its own activity of generating the idea proper.

This vital determinant having been received into the potential intellect, the potential intellect expresses *in conceptual terms* the nature of the thing represented concretely in the phantasm. In other words, the essential elements of the thing, abstracted from the phantasm by the agent intellect, are gathered together by the potential intellect into a *definition or abstract intellectual representation* of the thing. This conceptual definition is the completed or *formal intellectual cognitional image* of the

object, the 'expressed intelligible species (*species intelligibilis expressa*)' or *idea*. The formation of the 'idea' as an intellectual expression or representation of the thing is now complete. The intellect's abstract idea of man is 'rational animal,' and this idea is obviously something very different from the phantasm of 'man' in the synthetic sense or in the imagination; the phantasm is always concrete and material, while the idea is always abstract and conceptual.

The idea, immediately upon its formation, is a *potential universal*. The idea expresses the nature or essence of the thing, stripped of all individualizing conditions. As such, it represents what this thing has in common with all individuals of the same class. Before the intellect, however, is aware of this, it must compare this thing with things of the same type; it recognizes the fact that this nature is the same in all individuals of the class and then applies the idea to the whole class as a class and to every individual belonging to the class. The idea is now a *formal universal*. Universality is another feature of the idea which distinguishes it from the phantasm, because the phantasm, being derived from an individual thing, is always individualized and never universal.

Aristotelian-scholastic psychologists disagree among themselves as to whether the agent intellect and the potential intellect are two really distinct powers or two phases of one and the same fundamental power. Similarly, they disagree as to whether the phantasm is an (instrumental) efficient 'cause in the production of an idea or merely a necessarily required 'condition.' Furthermore, they disagree as to whether the 'impressed intelligible

species' and the 'expressed intelligible species' are really distinct from each other or merely two aspects of one and the same reality. These are abstruse problems which need not detain us.

The aristotelian-scholastic ideogeny, as here described, is an *ideological theory* which attempts to explain the process of the formation of ideas in the human mind, and as such it must be judged.

Understanding and Reason

We understand some things directly, because they are self-evident to the mind. Among these are the ideas we acquire through the direct perception of things, as when we interpret the things immediately presented to us by the phantasm in sensory experience; we need no 'reasoning' process to understand them. In a similar manner, we understand the meaning of *first principles* and perceive their truth and validity, without the necessity of proving them; they are immediately evident. Such principles are, for example, the Principle of Identity, the Principle of Contradiction, the Principle of Excluded Middle. The power of the mind which perceives the truth and validity of ideas and principles on the basis of direct and immediate evidence is termed *understanding*.

Some ideas, principles, and judgments, however, are not self-evident. They are *derived ideas, principles, and judgments*, the result of a process of elaboration and demonstration from previously acquired ideas, principles, and judgments, and are known through 'mediate inference'

on the basis of definite reasons and proofs. This process is termed 'reasoning,' and the power of the mind which perceives the truth and validity of derived ideas, principles, and judgments on the basis of indirect and mediate evidence is termed reason.

The question then arises: *Are understanding and reason two distinct powers of the intellect, or are they merely two aspects of one and the same intellect?*

There have been some *differences of view* on the nature of understanding and reason. According to Kant, it is the function of the understanding to cognize the phenomena of experience and to arrange the material of experience by means of the innate forms of the categories; and it is the function of reason to conclude from the conditioned to the unconditioned by means of the innate forms of the ideas of 'soul,' 'world,' and 'God.' He seems to view the two as distinct powers. According to *Jacobi*, the understanding is the capacity to know the sensory world, while reason is the capacity to know the supra-sensory realities (God, soul, essence, etc.) by means of a sort of faith without intellectual insight. According to *Hermes*, we know the data of experience by means of the ideas of the understanding, while the ideas of reason enable us to apprehend that which is known in its grounds and causes. A view, similar to that of *Hermes*, was held by *Gunther*.

We hold that understanding and reason are *really identical with the intellect* and merely designate two aspects of one and the same cognitive power.

Understanding and reason both have the same proper, connatural, immediate *object*, namely, the sensible in an

abstract form. They differ only in this that cognition through understanding is immediate, based on the self-evidence of fundamental ideas and principles while the cognition through reason is mediate, based ultimately on the self-evidence of the fundamental ideas and principles from which this cognition is derived. The 'mode' of knowledge is different, but the 'kind' of knowledge is the same. The formal object of understanding and reason being the same, there is no need to consider them as really distinct powers. Again, reason is to understanding as the *imperfect to the perfect*. The essence of all cognition is that things become evident to the knowing subject. Cognition is perfect, when the intellect 'knows' things directly and immediately; it is imperfect, when the intellect must seek reasons and grounds to make them known. Now, the cognition of the understanding is of the first type, while the cognition of reason is of the second type. It is only because of the weakness and limitation of the human intellect that it cannot acquire a full knowledge of all things through direct intellectual perception, but must 'conclude' to their existence by a process of reasoning. Imperfection of cognition, however, does not necessitate a distinct power.

Intellectual Memory

While treating of the sensory memory, it was pointed out that modern psychologists, as a rule, bulk together sensory and intellectual material without distinction in their investigation of human memory. They seem to take it for granted that memory is a single power. This concept of

memory is erroneous. Besides sensory memory, man possesses an *intellectual memory*.

We not only recall and recognize past items of sensory experience, but also items of experience and knowledge which are definitely *supra-sensory* in character.

Since *ideas are abstract and universal*, they cannot be the product of a sensory process and they cannot be stored in a sensory memory. Everything in the sensory memory is concrete and particular, affected by the material conditions of the sensations and of the phantasms of the synthetic sense, just as the latter are affected by the material conditions of the physical things from which they are derived. The *judgments, principles, and laws* which constitute intellectual knowledge and science, even when they pertain to the physical world, are meaningful interpretations, not sensory representations, of reality, and as such far exceed the capacity of the senses and of sensory memory. For example, the definitions, rules, and methods of logic cannot be perceived by the senses, because they are mental realities which emit no physical stimuli and therefore cannot affect the senses; no sensory image of their 'meaning' can be made by the synthetic sense, stored, recalled, and then be recognized by the sensory memory. The truth of judgments and inferences possesses no sensory qualities which could possibly be imaged, but is a matter of intellectual insight into the supra-sensory relations existing between ideas and judgments. We are forced, therefore, to conclude that intellectual memory exists and that it is a power really distinct from sensory memory.

This conclusion is confirmed by *experimental psychology*, although little experimental work has been done to separate the sensory and intellectual factors of memory. Certain facts point definitely to the existence of two kinds of memory, one based on sensory experience and the other on intellectual apprehension.

The *learning of meaningful material* is achieved far more easily than that of nonsense syllables, words, and mere numbers. Ebbinghaus (1885) discovered that we expend only one-tenth as much energy in learning meaningful material as we do for the same amount of meaningless material. His findings were verified by Binet, Henri, Neumann, Reed, and many other investigators. If memory involved nothing more than the recall and recognition of certain printed letters and numbers, it should make no difference whether their combinations contained a meaning or not, because the sensory image would be equivalently the same in all instances. The presence or absence of meaning, however, makes a decided difference. Since the difference cannot be accounted for by the senses and the sensory memory, the difference must be due to the intellect and the intellectual memory.

Similarly, the *curve of forgetting* is much more rapid and much more steadily downward for nonsense material than it is for meaningful material. Intellectual insight makes a great difference in this respect, as studies by S. Austin, A. G. Dietze, G. E. Jones, R. A. Davis, C. C. Moore, and others, conclusively show.

L. V. Zankov, in tests made on morons, discovered that they experienced a sudden development of intellectual or

'logical' memory when about ten or eleven years of age, due to an awakening of intellectual insight at that period, while no change occurred in their rote memory.

Facts of this kind and of a similar nature point to two types of memory. One is sensory, where learning depends on the repetition of sensory impressions; the other is intellectual, where learning depends on the understanding of non-sensory logical relations.

Sensory and intellectual memory, however, are not totally independent. On the contrary, the intellectual memory, to a great extent, is *dependent on the sensory memory*. Intellectual knowledge has its origin in sensory experience, and ideas are derived from phantasms through abstraction. Due to this intimate relationship between sensory and intellectual processes, their mutual influence is bound to be deep and lasting. Any pathological disturbance of the sensory memory will naturally also effect intellectual memory. Word-blindness, for example, brought on by disease or injury of the brain, interferes with recall and recognition of words and their meaning; but it does not interfere with the understanding and recognition of logical relations, ideas, and principles as such.

According to the principle that 'entities should not be multiplied without good reason,' we accept the view that *intellectual memory is identical with the intellect itself*, and not a power distinct from the intellect. The knowledge retained by the memory and then revived at a later period is identical with that originally acquired by the intellect, and we are conscious that this knowledge is the same. There seems to be no valid reason for assuming that intellectual

knowledge is 'acquired' by one power and 'retained' by another. On the other hand, it is logical to assume that the knowledge, which at first was actual, simply becomes 'habitual' by being reduced to the condition of a *trace* or *disposition* in the intellect, capable of being activated anew and recognized as having been present before. Nothing more seems to be required.

If we now summarize the salient facts pertaining to the origin and nature of ideas, we note the following *stages in the developmental process*:

First, the external things send forth certain forms of energy which impinge on the sense organs. The vital subject responds through its sense mechanism with sensations, and these sensations are a rudimentary cognitional image of the external thing. This cognitional image is 'rudimentary,' because the sensations, as such, are only isolated items of experience.

Second, in the presence of these sensations, the synthetic sense combines them into a perceptual whole by forming them into a unified phantasm and referring them to the external thing which they represent. The phantasm is the completed or formal cognitional image which makes the thing known to the knower in a sensory manner. The imagination conserves the content of the phantasm as a dispositional image which can be revived and recognized by the sensory memory.

Third, when presented with the phantasm or image, the agent intellect abstracts the essential elements of the thing from the concrete conditions in which they are found in the phantasm or image, thereby making the phantasm or image

intelligible. These abstracted essential elements are the rudimentary intelligible cognitional image of the object.

Fourth, the agent intellect presents these abstracted essential elements to the potential intellect, which now goes into action and mentally expresses this intelligible content in conceptual terms, thereby forming the idea of the thing in an abstract and universal manner. The 'idea' is the completed or formal cognitional image of the external thing in the intellect and is stored away in the intellectual memory for future recall and identification.

While much of this is speculation, the theory gives a rather neat explanation of the deep problem of bridging the sensory and intellectual processes involved in the origin and development of ideas.

Summary of Chapter XIV

This is an account of ideogeny according to Aristotle and the scholastics.

1. *Intellect and Thing.* There is nothing in the intellect which was not first (in some manner) in the senses. There are no innate ideas; they have their source outside the intellect; the intellect must derive them from the things. Hence a union between intellect and thing by means of a *cognitional image* is demanded.

2. *Role of the External Senses.* In the presence of the stimuli proceeding from the thing, the sentient subject actively produces within itself the vital response of *sensations*. These sensations represent the thing and are the *rudimentary cognitional image* of the thing, the 'impressed sensible image.'

3. *Role of the Internal Senses.* The central or synthetic sense combines the isolated sense qualities into a perceptual whole and refers them to the same definite thing. The result is the phantasm, the completed or *formal cognitional image* or 'expressed sensible image' of the thing. The phantasm completes the knowledge of the thing on the sensory level. The phantasm is taken over by the imagination as an image which can be recalled and can be identified by the sensory memory.

4. *Agent Intellect.* The intellect forms its ideas by turning its attention upon the content of the phantasm either of the synthetic sense or of the imagination. By means of abstraction, the intellect grasps the essential elements of

the thing represented in the phantasm, leaving aside the individualizing material determinations, thereby making the phantasm 'intelligible.' This power or capacity of the intellect, whereby it actively modifies itself so as to represent within itself in an abstract manner what is concretely represented in the phantasm, is termed the *active* or *agent intellect*. The result of this abstractive process is the *impressed intelligible cognitional image*, the 'idea' in a rudimentary form.

5. *The' Potential intellect*. The power or capacity of the mind to express the essence of the represented thing in an 'idea' or 'concept' is termed the *Potential intellect*. The essential elements, after being abstracted from the phantasm, are presented by the agent intellect to the potential intellect; the latter expresses the elements in conceptual terms by gathering them together into a *definition* or *abstract intellectual representation* of the thing. This 'idea' is the completed or *formal intellectual cognitional image* of the thing ('expressed intelligible species').

6. *Understanding and Reason*. The power of the intellect which perceives the truth and validity of ideas and principles on the basis of direct and immediate evidence is termed *understanding*. The power of the intellect which perceives the truth and validity of ideas and principles on the basis of indirect and mediate evidence is termed reason. They are not distinct powers, but merely two aspects of one and the same intellect.

7. *Intellectual Memory*. Ideas are abstract and universal and as such supra-sensory. The judgments, principles, and

laws which constitute intellectual knowledge and science are meaningful interpretations, not sensory representations, of reality. Such mental items, therefore, exceed the capacity of the senses and of sensory memory. Hence, *intellectual memory* must be really distinct from sensory memory. Intellectual memory is identical with the intellect itself and not a power distinct from the intellect.

Chapter 15

VOLITION

SO FAR WE HAVE DISCUSSED THE MENTAL LIFE OF MAN AS IT appears in sense-perception, in sensuous appetency, and in intellection. Sense-perception makes us acquainted with the objects of the universe and with our own bodily states and conditions. Sensuous appetency seeks to bring us into union with objects which are recognized as sensuously good for us and to remove us from objects which are recognized as sensuously evil. The intellect penetrates the concrete appearances of things and cognizes the sensible in an abstract and universal manner, thereby arriving at a knowledge of 'what things are.'

There is still another phase of man's mental life which must be added to these. It is *volition*, the activity of the *will*. Just as sensuous appetency is the counterpart of sense-perception, so volition is the counterpart of intellection. There are two kinds of cognition, and there are two kinds of appetition.

The Concept of the Will

The best approach toward an understanding of the will is an examination of those types of experiences which reveal the acts of the will in everyday life. During the course of a day we set our will in action hundreds of times. Here are a few characteristic samples.

The alarm clock rings in the morning, and the father of the family becomes awake. The bed is comfortable, he is drowsy, and he feels a strong urge to snatch a little more sleep; however, he *resists* the impulse and gets up. He goes over to the wardrobe and, after a few moments' hesitation, *selects* his brown suit. At the breakfast table he makes a number of *decisions* as to quantity and quality of food; although he had *resolved* long ago to take only light breakfasts and *usually kept his resolution*, this morning, being rather hungry, *he changes his resolution* and eats a large portion of ham and eggs instead of the customary cereal and toast. Being of considerable corpulence, he *detests* walking and *prefers* to use the car to go to business; nevertheless, *desiring* to reduce his weight by some form of exercise and consenting to his wife's advice, he strolls to his office. Upon entering the office, he notices that his secretary is wearing a canary-yellow ensemble. He *disapproves* of this type of garb during business hours and *feels tempted* to make a caustic remark; on second thought, however, he *refrains* and, *forcing himself* to be pleasant, extends the usual greeting. Opening his mail, he reads the letter of a customer who makes a number of very unreasonable demands. He *hates* the tone of the letter and, momentarily *yielding* to his emotions, utters a few explosive epithets; on seeing the startled expression on the face of

the secretary, he expresses his *regret* over his *impulsive action*, admitting that he *should have had better control* over himself. The letter annoys him greatly. He *feels inclined* to give a point-blank *refusal* to the demands and to answer in a revengeful spirit of pique; but he also realizes that he *ought* to overlook the truculent tone of the letter from a *motive* of Christian charity and patience; finally, he needs the profits to be derived from this business for rearing his growing family which he *loves* very devotedly. What shall he do? It is a momentous decision for him to make, and he knows he *should not* act hastily in the matter. He deliberates for some time about the course he should pursue and then *decides*, for the sake of the welfare of his family, to accede to the demands. Having made his *choice*, he thinks he deserves a *reward* for his virtuous act, selects one of three cigars he carries in his pocket, lights it, and smokes contentedly in the realization that he has exercised great will power. And so the day passes, similar incidents occurring continuously.

In this brief description we notice a number of attitudes and acts of the will. Emotions and sensory impulses are present, and so are considerations of an intellectual, social, and moral character. The person in question makes decisions to act and not to act, to perform one kind of act rather than another; he makes a selection between various objects of equivalent value, and he chooses between moral good and moral evil. He is conscious of influencing motives, but also of freedom of choice and responsibility of action; he acts on impulse, but he also acts after serious deliberation. His intellect proposes different motives and methods of

procedure, but he himself determines the issue by making whatever decision and choice he prefers.

‘Resisting,’ ‘selecting,’ ‘deciding,’ ‘resolving,’ ‘detesting,’ ‘preferring,’ ‘desiring,’ ‘consenting,’ ‘approving,’ ‘disapproving,’ ‘feeling tempted,’ ‘refraining,’ ‘forcing oneself,’ ‘hating,’ ‘yielding,’ ‘regretting,’ ‘losing control,’ ‘feeling inclined,’ ‘refusing,’ ‘loving,’ ‘acceding,’ ‘choosing’ — all these mental states and experiences involve attitudes or acts of the will with reference to objects, persons, and situations. The feature common to all such states and experiences is a conscious inclination toward an intellectually perceived good and a conscious aversion from an intellectually perceived evil.

Whatever may be our ultimate judgment concerning the *will* and its nature, the will is conceived and defined as *rational appetency or the power to strive for an intellectually perceived good and to shun an intellectually perceived evil*. The exercise of willing is termed ‘volition.’

The Object of the Will

Experience shows that we strive for *material*, concrete, particular objects which seem good to us, such as food, sleep, money, exercise, health, and so forth. Over and above the sensible good, we strive also for the things of a supra-sensible and *spiritual* character, such as scientific knowledge, virtue, fame, esteem, and the like. Since our intellect abstracts the universal concept of ‘good in general’ from the single good objects, we strive for *good in general*,

without a view toward any particular kind or class of objects.

When we perceive that this universal concept of good is realized in any 'particular' good, we can strive for this particular good, because it partakes of the general good which we have come to know and toward which the will inclines. Since we find the concept of the 'good in general' exemplified in material and immaterial things, the will is capable of striving for both classes of objects.

To have a universal concept of the 'good in general,' is an *intellectual* acquisition. Man abstracts that which is 'good' in all types of objects classified as 'good' and expresses the content of the 'good' in conceptual terms, formulating an intellectual definition of the 'good.' Something is 'good,' if it is suitable to a thing; abstractly speaking, *goodness* is the *suitability of a thing to a natural tendency or appetency*.

The general concept of the 'good' leads us to a consideration of what is the 'adequate' and the 'formal' object of the will.

The *adequate object* of the human will is *everything that is good*.

Every conscious *appetitive* power or appetency extends as far as its corresponding *cognitive* power. Sensory appetency can strive only for something that is a sensible good; it is limited to the concrete, material, particular, because the senses are restricted in their knowing capacity to the concrete, material, particular. The human will, however, has no such limitations. The intellect, absolutely speaking, is capable of knowing whatever is (ontologically) true. And since everything that is (ontologically) true is also

(ontologically) good,¹ the intellect can apprehend all things under the aspect of 'goodness,' and the will, in consequence of this, can embrace with its striving power anything and everything that contains reality of whatever kind. *Everything*, therefore, that possesses 'being' and *is a being* (God and creature, the material and immaterial) *belongs to the adequate object of the will* as a rational appetency, because every being is a 'good' in some form or other.

The *formal object* of the human will is *the good as good* (*bonum qua tale*), provided it be *suitable to the willing subject* in some manner.

By this assertion we claim that the will cannot desire a good object in so far as it is an evil in any way, but only *in so far as it is a good strictly as such*. Nor can the will ever desire an evil precisely as an evil. Whatever the will desires it must desire under the aspect of a 'good.'

The will is an appetitive power, and it is the essence of an appetitive power to strive for things, so as to bring about a union between the striving subject and the desired thing. Now, if it were possible for an appetitive power to strive for the evil as such and shun the good as such, it would by its very nature seek the *destruction* of the subject. An appetitive power of this kind, however, would be a perverse and contradictory reality, a useless and destructive tendency, existing in man as an integral part of his constitution; the creation of such a being, however, would be contrary to the wisdom of the Creator.

Again, the will is given to man as the rational complement of his intellect, in order that he may strive in a better manner than the sentiently cognitive brute for that

which is conducive to his rational nature. Now, the natural tendencies of the brute are directed exclusively toward the good. Consequently, the human will also has as its natural object the good exclusively, otherwise it would be *less perfect* than the sensory appetency of the *brute*; in fact, it would be much *worse*, because the will dominates the sensory appetency in man and can hinder it from executing its natural tendencies. It follows, then, that the proper and formal object of the will is the 'good as such.'

In order, however, that the will be able to strive actually and effectively for a thing, this thing must be a *good for the subject* using the will; it must be *suitable* in some manner to the subject and must be intellectually perceived as such by the subject. Only the good is desirable, and it is desirable only because it assists in some manner toward perfecting the individual person who strives for it. After all, the will is a personal power, given for the benefit of the person possessing it; otherwise there would be no relation between will and object for this particular person.

The will itself is said to be blind, because it is not a cognitive power; it is an appetency or appetitive power. The intellect must furnish the necessary judgment as to whether a particular thing is a good or evil for the person; the will then strives for the good and shuns the evil. Ultimately, of course, it is the *human person who thinks and wills*; the human person perceives the goodness in a thing with his intellect and strives for it with his will, perceives the evil in a thing with his intellect and shuns it with his will.

Types of the Good

In as much as the adequate object of the will is everything that is good, it is well to know the different classes of the good. The main divisions of classification are as follows:

Ontological, Physical, Moral Good. A thing is an *ontological good*, when it is a good in its very entity or reality. Every being, since it possesses a certain amount of entity or reality, is an ontological good, because its entity or reality is suitable for the tendency of its own nature to be what it is and to perfect itself and to retain its perfection.

A thing is a *physical good*, when it satisfies the demand of the *nature of a being*: Each being has its own specific and individual nature, and as such it has a very definite end and purpose. What suits one nature does not necessarily suit another. The physical exigencies of man, for instance, differ from those of a horse, a cow, a bird, a fish, or a tree. Whatever suits such a specific or individual nature, perfecting it in some way, is a physical good. Thus, for man sight, hearing, well-functioning organs of digestion, etc., are physical goods.

A thing is a *moral good*, when it has everything demanded of it by the *moral law*. An action, for example, may be physically perfect, but it may contravene the moral law; in that case, it would be physically good but morally evil.

Absolute and Relative Good. An *absolute good* is anything suitable *to a being itself*, irrespective of other beings. Any reality which a being possesses, whether substantial or accidental, is an absolute good for that being;

in man, for example, all bodily structures, organs, powers, and functions are absolute goods. A *relative* good is anything which is suitable *to another being*; food, drink, clothes, shelter, etc., are relative goods for man.

Objective and Subjective Good. An objective good is anything that is a good in *itself*. Any absolute or relative good, as just defined, is an objective good in this sense. By *subjective* good we mean the actual possession of an objective good. An artistic painting, for instance, is an objective good in itself; it becomes a subjective good for me, if I acquire it as my own.

Real and Apparent Good. A good is *real*, when it is judged to be good for a being, and it *actually is* good for that particular being. The nature, bodily limbs, senses, intellect, will, etc., are real goods for man. Something is an apparent good, when it is judged to be good for a being, but it is actually not good for it. A certain kind of food many seem a 'real' good for a critically ill patient, but it may be very harmful; under the circumstances it is an apparent good, even though it is something which, in itself and for itself, is ontologically good. Similarly, pleasure is a physical good; but if its enjoyment is in opposition to the moral law, it is an 'apparent' rather than a 'real' good, because the moral law must stand higher in man's estimation than pleasure.

Disinterested, Delectable, and Useful Good. A *disinterested* good (*bonum honestum*) is any good considered merely as giving perfection, irrespectively of any pleasure derived through its acquisition or from its possession; health, knowledge, virtue are such. A *delectable* good (*bonum delectabile*) is a relative good which gives

pleasure and enjoyment. What is really desirable here is the thing itself which gives *pleasure*; oftentimes, however, the pleasure itself becomes the object of desire. Food, drink, companionship, the use of sex, etc., belong to this class. A *useful* good (*bonum utile*) is a relative good which is desired as a *means* to acquire perfection or pleasure; there is always an ulterior end in view when a good of this kind is desired. A game of golf, for example, is a useful good, desired as a means to promote one's health, to gain fame, to obtain the pleasure of companionship, and so on.

Every good is a *value*. Value is that which is 'perfect' or 'perfective.' Value, considered as something which is perfect, coincides with the absolute good, because it is identical with the reality, substantial and accidental, which a being possesses. Considered as something perfective, it coincides with the relative good, because its perfection is a good for another being. Everything, therefore, has 'value' in so far as it is a good for itself or for another. 'Goodness' and 'value' are thus seen to be synonymous terms, when viewed in their ultimate, metaphysical implications.

Evil and the Will

Evil is the antithesis of 'good.' Evil is the unsuitability of something for a natural tendency or appetency. It is not a being, but it is not a mere absence of being. It is the absence of a reality which ought to be present, of a reality due to a thing; it is a defect, a privation of reality — the *privation of a required good*.

In view of what has been said about the good as the formal object of the will, it should be fairly obvious that the will cannot desire the *evil as such*. If a being could desire an evil as such, it would strive for its own harm; however, according to all laws of nature, every being tends to preserve its own entity and perfection. The will naturally shuns the evil, just as it naturally desires the good; by the very fact that it is intrinsically necessitated to strive for the good, it is also intrinsically necessitated to shun the evil.

An *objection* is frequently advanced against this view. The opponents point out that people desire things that are *physically harmful and morally evil*. People eat and drink to excess, even though they realize that they are inflicting serious injury upon their system; they desire the amputation of a diseased member of their body; they seek illicit sex pleasure, well knowing that they are committing an immoral act. These and similar facts cannot be disputed.

The *answer* to this is simple. All creatural things are finite, limited in entity and consequently limited in their goodness. Because of this natural limitation of goodness, they are *not suitable* to the specific and individual nature of every other being; and in this respect they are an evil for some beings. In other words, creatural beings are ontologically good; but they are a 'relative evil' to a great many other beings, because they are unsuitable to them. When, therefore, a creatural being is desired, it is desired *because of the goodness* present in it, and not because it is a relative evil. In all such cases, the evil is the 'material' and 'indirect' object of the will, while the good is the 'formal' and 'direct' object of the will. We must remember that the

will is blind and relies on the judgment of the intellect as to whether something is good or evil. The intellect, however, is fallible and often erroneously considers some things as altogether good and desirable which are only partially so or only so in certain circumstances and under certain conditions. Hence, whenever the will strives for something that is evil, it does so solely *under the aspect of a good*.

Experience proves this fact. We may know, for instance, that excess in drink will eventually ruin our health; if we nevertheless drink to excess, we do so because the pleasure derived from drinking is a present physical good which, as such, is desirable. Where the attainment of a physical good contravenes the moral law, we simply choose the minor (physical) good in preference to the greater (moral) good. Similarly, we choose a minor evil in preference to a greater evil, as when we decide to undergo a painful operation rather than die; the operation, however, is not chosen because it is an evil in itself, but because it is, compared with prolonged pain or death, a relative good which will lead to health and well-being for the organism as a whole. Even a person committing suicide does not strive for death because it is an evil, nor does he seek to take his life because he desires to rid himself of a good; he commits suicide because he considers the freedom from shame or sickness or poverty a greater good than living in shame, sickness, or poverty. 'Freedom from misery' is the good for which he is really striving; death is considered to be a useful good to bring about this freedom, a means toward a beneficial end, and under this aspect the suicide strives for

a good and not for an evil. He is mistaken, of course, in his judgment; but that is beside the point.

In all instances where persons seem to strive for an evil, a close examination will show that they desire a 'real' good or, at the very least, an 'apparent' good in the object of their choice. The extreme case may happen that someone deliberately chooses what he knows is an evil for himself; he seems to make his choice out of sheer perverseness of will, entirely against his better judgment. Even in such a case, however, he does not seek an outright evil recognized as such. He chooses an evil through *pride in his ability to choose it*; the exercise of his pride and of his will is the motive of his action, and that appears to be a good for him worthy of choice.

Motive and Motivation

The activity of the will is closely linked to *desire*. Desire is a longing aroused by the conscious representation of an absent good. Some object or experience is represented to the subject and is recognized as a possible physical, intellectual, or moral 'good.' The object or experience thus represented produces in the subject an attraction toward this object or experience, with the result that the will has a natural tendency to seek its attainment; the will is 'moved' toward the attractive object or experience and is said to be influenced by a 'motive.'

A *motive*, then, is anything which prompts or excites the will to action. The object or experience must contain some sort of objective goodness in itself, in order to become a

motive for the will, because only the good is desirable. But the mere presence of objective goodness alone does not suffice to make it a motive. The object or experience must be *apprehended* by the intellect as something good and therefore desirable, for nothing is willed except it be known (*nihil volitum nisi cognitum*). A double factor is thus involved in a motive: the objective factor of the goodness of the object or experience, and the subjective factor of the intellectual knowledge of this goodness on the part of the willing subject. Unless the object or experience be a good in itself, it cannot be desired; and unless the subject knows of its goodness, the subject cannot desire it. The good desired is thus a 'value.' And we can define a *motive as an appreciated value realizable through an act of volition.*

Since the will is entirely dependent on the intellect for the recognition of value (goodness), it is evident that the attractiveness of the motive lies more in the manner in which it is presented by the intellect than in the objective goodness. The objective goodness of one kind of object or experience may be far greater than that of another; yet, if the greater objective value is not recognized as such or not recognized at all, the minor value will have greater force. Similarly, a person may concentrate his attention upon one value, refusing to consider any other; under the circumstances the one value alone will act as a motive. Much, therefore, depends upon the actual knowledge, the intellectual and moral training, and the general temperament of the individual person, whether an object or experience will be a strong or weak motive or even a motive at all. Value is relative to the person desiring it, and for this

reason the *intellectual presentation* of value as a motive is a most important factor in willing.

Motives may be *physical, intellectual, or moral*. Material objects and sensory experiences are physical goods, and as such they are 'physical' motives for volition; examples are food, shelter, wealth, the pleasures of sense. Intellectual attainments also influence the will to action and are 'intellectual' motives; knowledge and science are such values. Objects and experiences, which are commanded by the moral law or are in conformity with it, possess moral value and are 'moral' motives; the virtues belong to this class. We also differentiate between *inner* and *outer* motives. 'Inner' motives regard the self and its perfection, as when we strive for knowledge for the development of our mind; 'outer' motives regard other beings, as when a father strives for wealth in order to support his family. In general, there are as many kinds of motives as there are *kinds of goods*.

By *motivation* is meant the arousal of the will from a state of inaction into a state of action. Modern psychology includes under the heading of motivation various kinds of obscure psycho-somatic conditions, as feelings, organic movements, unconscious and subconscious drives, etc. Such conditions are more in the nature of general sets or attitudes than motives properly so-called. As explained above, a value, in order to be a genuine motive for the will to act, must be appreciated as a value, and hence must *enter consciousness* and be perceived as something desirable. Conscious apprehension is the first condition for motivation. The second condition is that a motive have

sufficient strength to produce volition. We often hesitate to make a decision; it is then necessary to strengthen the motive, so as to help the will overcome its hesitancy. We may give more attention to the good under consideration, examining it from various viewpoints, and thereby convince ourselves that the value is really greater than was at first supposed. Or, we may compare a good with related evils, enhancing the value by contrast. Or, we may induce the will to strive for a certain good by adding some other motives, so that the weak motive receives strength from participation with stronger motives. Finally, we recall past experiences or resolutions, thus influencing the will to act, even though the present motive appears weak and insufficient of itself.

The more powerful the motives, the easier it is for the will to pass from indecision to decision. It must be remembered, however, that motives are only preliminary *conditions* of volition; they 'appeal' to the person to exercise his will. Motives reside in the intellect; the intellect makes the *practical judgment* that this or that thing is desirable and thereby elicits the act of the will. Motives thus set a goal for the striving of the will, and the practical judgment brings the goal into relation with the will. When conflicting motives are present, the relative objective strength of the motives does not, strictly speaking, decide the issue and compel the will to act; it is the person who decides which motive shall have the greatest weight.

Natural and Deliberate Volition

The internal acts of the will are by no means all alike. Volition appears in different modes, giving rise to distinct *types*. The two main types are *natural* and *deliberate* volition.

It lies in the very essence of the will as an appetency to incline toward the good and, as a consequence, to shun the evil. Its ultimate end and purpose is to strive for *happiness* or *beatitude*. By happiness or beatitude is meant a perfect state acquired through the possession of all that is good for a being. Such a state excludes any and every kind of evil; conversely, it embraces every kind of good required for the complete satisfaction and perfection of the nature of the respective being.

The will cannot be indifferent toward happiness. If the intellect proposes happiness to the will as an object for its volition, the will must approve of it and consent to it; if the will acts at all, it must incline toward it with love and desire. It is *not* free in this respect. Man seeks his happiness with necessity, not through choice. Since the good is the formal object of the will, and since happiness or beatitude is fullness of good, the will, by its very nature, must strive for it. Because of this fact, this type of volition is termed *natural* volition. The only choice in this matter within the power of the will is to divert the attention of the intellect away from the thought of happiness and force it to think of something else. Under no circumstances, however, can the will be really indifferent toward happiness; much less can the will's attitude toward it be one of displeasure or aversion, because that would contradict the inmost nature of the will as a rational appetitive power of man.

Generally speaking, we experience the possibility of preference and choice in volition, when values are presented to the will for acceptance. As stated before, creatural beings possess only limited goodness and they are not suitable for every kind of being to the same degree; they may be desirable from one viewpoint and undesirable from another. Particular objects and experiences satisfy our wants only partially. When such values confront the intellect and the will, none of them are so attractive as to compel acceptance to the exclusion of the rest. The situation demands an examination of values, a weighing of motives, a consideration of alternatives. After some *deliberation* over the respective merits of the particular values proposed, a preferential choice is made among these conflicting values, and the will goes into action. This type of volition, which results in consequence of a deliberation, is termed *deliberate* volition.

When a preference is given to a value after careful deliberation, so that we are conscious of the reasons for choosing as we do, our choice is said to be *reasonable*. When we have not the time for careful deliberation, or are not inclined to give much thought to reasons for preference, and resolve our hesitancy by making an impulsive and offhand decision, our choice is said to be *impetuous*. When we make a decision through force of habit, by following the line of least resistance, by submissively giving way to other people's suggestions, and so forth, our choice is said to be *acquiescent*. When we decide on a course of action which is important, beset with difficulties, and which involves serious and prolonged effort,

our choice is said to be *grave*. And when our choice runs counter to cherished interests and demands a painful renunciation and struggle, all for the sake of a duty to be performed, our choice is said to be conscientious.²

Voluntary Control

By *voluntary control* we understand the control which the will exercises over the powers and actions of the human organism. This control, as it is commonly conceived, is exercised by the will by means of a 'command': the will issues a command to a power to go into action, and the action follows.

Everyday *experience* convinces us that we have voluntary control over powers and actions of our own person. Through an act of the will we direct the course of our thoughts in solving a problem; we set the associative mechanism of the imagination going, consciously combining and dissociating images according to a definite plan; we control the movements of our eyes and of its focusing apparatus, forcing them to look at the objects we desire to inspect; we command our tongue and lips to speak, our legs to walk or run, our hands to write or type or manipulate a machine, our body to stand erect or lie down or bend forward; and so on, with a hundred and one different kinds of actions.

Voluntary control, however, is not universal, nor is it uniform in effectiveness. Some activities of the human body are *not subject* to voluntary control. We need but mention the activity which takes place in the *cells*. The functions of

the *vegetative organs* can be controlled only *indirectly* by the will. The metabolic processes go forward day and night without interruption. The will cannot stop the beat of the heart, the digestion of the stomach, or the secretion of the kidneys by any direct command. In directly it can influence their action; for example, through the withholding or selection of food materials, the injection of drugs, the arousal of emotional states, over-exercise, dissipation, etc. We have also indirect control over the functions of the *external senses*, mainly by control of the stimuli which activate the senses. Once the stimuli have impinged upon the sense organs, we cannot hinder them from carrying out their proper functions; but it is possible for us to control, at least in many instances and to a considerable extent, the chemical and physical agencies which influence these organs and thereby also their functions.

We have *direct*, though not absolute, control over *bodily movements* through the striped muscles, over the activities of the *internal senses*, and over the *intellect*. That we normally control the movements of our bodily members in walking, writing, etc., by a direct act of volition, is evident from experience. Though much of the activity of the synthetic sense, the imagination, and sensory memory is spontaneous, their activity is also to a great extent subject to the direct control of the will. Regarding the intellect. the will cannot, of course, compel it to deny an obvious fact or principle, nor can the will force it to accept contradiction. It can and does, however, direct the attention of the intellect to this or that fact or principle, and thereby it directly controls its activity along certain lines of thought. Similarly,

when the evidence is conflicting and certitude is impossible, the will can influence the intellect to resolve its doubts by forming a definite opinion. It happens quite frequently that the intellect passes a judgment on a matter, not so much according to objective evidence, but according to the inclinations and desires of the will. Shakespeare expressed this fact saying that "The wish is father to the thought." Many erroneous opinions, snap judgments, hasty generalizations, and prejudices can be traced to the direct control of the will over the activity of the intellect.

Concerning voluntary movements, one phenomenon deserves particular consideration; it is the *gradual mechanization* of such movements under the influence of volition. Many movements involve the coordinated activity of a large number of nerves and muscles in an intricate series of part movements. Psychologists speak of such a neuro-muscular co-ordination as a *kinetic unit*. Kinetic units are present in movements of everyday life, as walking, lifting, grasping articles with the hands, etc., and in skilled actions, as typewriting, playing a musical instrument, pole-vaulting, etc. One need but watch an expert musician play a piece on a piano, in order to observe the marvelous co-ordination of nerves and muscles required for this performance. The remarkable thing about these movements is the fact that the will merely intends the *series in general*, and then the movements follow almost unconsciously and mechanically; oftentimes, as we know, the performance is actually carried out unconsciously. How are kinetic units established?

Some kinetic units are not acquired and learned; they are *hereditary*. John B. Watson and M. G. Blanton, through observations made on infants, have established the fact that children possess some kinetic units from birth as a native endowment. Examples are: the neuro-muscular co-ordination required to fixate and follow a moving light or object with the eyes, grasping an object with the whole hand, kicking, and so forth. In most cases, however, the component parts of a complicated movement must be pieced together by *direct volition*. Repetition fuses the component parts into a kinetic unit, so that less and less attention and voluntary control need be given to the component parts. Frequent repetition then makes a habit of the entire movement. As a consequence, all that is needed in order to carry out the entire movement, without any conscious attention to the details, is to make an initial act of the will intending the movement as a whole, and the neuro-muscular system takes care of the rest. Voluntary movement has thus become gradually 'mechanized.' We intend, for instance, to walk to a friend's house; having willed the action, we automatically walk along the street, our attention being engrossed by the things we see. Similarly, a pianist, after deciding to play, let us say, the 'Humoresque,' renders the composition with flawless accuracy, practically unconscious of the movements of his arms and fingers while he imagines the melody.

Bodily movements, therefore, may be actually, virtually, or habitually voluntary. A movement is *actually* voluntary, when it is willed directly here and now, as when I decide at this moment to write these words. It is *virtually* voluntary,

when a particular movement is a component part of a kinetic unit and I will the entire unit; by deciding to perform the entire movement as a whole, I virtually will the component parts of the entire movement. When, for example, the entire movement of an extended stroll is actually willed, the single steps are virtually included in this general act of volition. A movement is *habitually* voluntary, when at present it is mechanized through a neuro-muscular co-ordination which, though built up on a former occasion through repetition by means of distinct voluntary acts, now carries out the movement automatically without attention and without conscious voluntary control. A stenographer, for example, acquires 'word-habits' which enable her to type entire words, even when conversing with someone. Kinetic units, except for the limited number which are inherited as native endowments, must be acquired through direct voluntary control. Once acquired, however, we need but will the *end-result* of the entire action; association and habit complete the action. Directing one's attention or volition to the component parts of the action nearly always exerts a disturbing and inhibiting influence upon its smooth performance. Kinetic units are but another illustration of the fact that man is an integral organism in which everything conspires toward his general well-being.

What N. Ach (1905, 1910) called *determining tendencies*, is of a similar character. In his experiments on volition, Ach discovered that the subjects, after making an act of the will or resolution to perform a certain task, carried out this task even when they no longer adverted to the resolution formerly made. Having accepted the task of

multiplying the numbers which would be flashed on a screen or of making a rhyme to a nonsense syllable when given, they performed the task, notwithstanding the fact that their mind was diverted at the time by other thoughts and they had forgotten about their former resolution. Ach rightly concluded that such results were intelligent operations and could not be accounted for by the mere association of images. Accordingly, he postulated the existence of some sort of psychic force which, acting subconsciously, proceeded from the resolution and carried out the task to a correct conclusion. This force he called a 'determining tendency.'

There seems, however, to be no need of postulating such a psychic force distinct from the will and other powers of the mind. J. Lindworsky³ (1922), an eminent authority on the will, opposed Ach's concept of the determining tendency as a new force. He pointed out that 'voluntary attention,' when applied to an image complex, is sufficient to explain the facts. Whenever we will something and include it in a specific resolution, we must turn the intellect toward the task intended, thereby giving attention to the objective of our willing. The image complex involved in the performance of the task is thus singled out and strengthened in preference to others. Kinetic units accompany such an image complex to a great extent. Since a particular image complex is thus favored, it will lead to the desired operation in consequence of the initial resolution, even when the resolution itself is not immediately present in consciousness. In this respect the

execution of the task resembles virtual or habitual voluntary actions.

The Existence of Volition

The question before us now is not the question of the freedom of the will; rather, it is the question whether *volition* exists as an operation distinct from previously considered and acknowledged mental states. It is also the question whether man possesses a *will* distinct from other mental powers. If volition is not a distinct type of operation, then the will does not exist as a distinct power or man; on the other hand, if volition is a distinct type of operation, then its existence also demands the will as the power from which it proceeds.

The existence of the will and of volition is denied or ignored by many modern psychologists. If they do speak of 'voluntary control' or 'voluntary action,' it is done in deference to popular views and expressions; their explanations show that they identify volition with some other elements of mental life which are decidedly not 'voluntary' in the philosophic sense of the term, namely, sensations, images, feelings, or sensory appetitions.

T. V. Moore⁴ sums up the evidence for the existence of volition as a distinct mental operation under the following comprehensive headings:

Facts of Attention. Practically all books on modern experimental psychology, when treating of the mental process of attention in man, distinguish between *involuntary* and *voluntary attention*. The facts themselves

are plain. If someone shrieks into our ear, or if a fire engine's siren wails past us on the street, or if we fall and hurt ourselves painfully, or if someone pushes us forcefully, or if a bright light is turned on when we are in a dark room, or if we inadvertently take a pinch of quinine into our mouth — our attention is drawn to the circumstances, no matter how occupied our mind may be. We simply cannot avoid noticing these things; we involuntarily give our attention to them, because they *force* themselves upon our attention. In many instances, however, our attention is *deliberately decided* by ourselves, *directed* toward something which is in no way conspicuous, and *personally controlled* throughout the duration of its existence. We can, for example, direct our attention upon a particular blade of grass, a particular page in a book, a particular spot on the wall, a particular person in a crowd, etc., and then deliberately direct it to a different blade, page, spot, person; and this is done simply because we decide to do so, without there being anything in these things to attract our attention in a special manner.

Resolving on a Task. When a task is proposed to us by somebody, or when we propose a task to ourselves, we are conscious that it rests with us to accept or refuse it. When we resolve to accept the task, we experience a certain *determination* on our part to carry out the task, and this determination is something very different from the accompanying sensations, images, feelings, and motives. These latter may drop out of consciousness after a while, but the determination of the resolution may persevere for hours, days, and even years, influencing the very course of

our life. Sensations, images, feelings, and intellectual acts of insight are fleeting realities, while the resolution is a persistent fact of mental life extending over and beyond these passing states.

Reaction-time Experiments. Psychologists have made experiments with subjects relative to the time required to make a choice to do something or not to do it, and to make a choice to do one thing or another thing. In all experiments of this kind, it was found that the subjects arrived first at a stage of readiness or preparedness to go into action, but the action itself would not follow until a distinct choice had been made and the command or fiat had been issued to proceed with the action. This '*command*' or '*fiat*' was distinct from an understanding of the various actions contemplated and the particular action chosen. The command was a distinct element in the total process.

Control of Emotions. While it is not possible to control our emotions directly, it is possible to control them indirectly, namely, by a direction of our attention. Bringing the causes of the emotion into the focus of our attention, intensifies the emotion, as when we think of the insult which causes our anger. However, when we concentrate our attention on the emotion itself and analyze it, our emotion evaporates rapidly. It is precisely the *effort to divert our attention away* from the cause of emotion toward the emotion itself that manifests voluntary control, because under these circumstances we work in opposition to the natural stimulus of the emotion.

Inhibition of impulses and Desires. Impulses and desires are the springs of action, and normally they lead to the

execution of the actions prompted by them. We observe this fact plainly in the brutes; they actively strive for the sensory good and actively shun the sensory evil. In so far as man has a sensory nature, he is on a par with the brutes and in many respects acts accordingly. Not always, however. Many times he curbs and *inhibits* his natural impulses and desires, often under conditions which entail great effort and sacrifice. Although the natural impulses and desires drive to action, the action fails to result. Man thus acts or desists from acting from a sense of duty or because of an ideal of conduct which he has set for himself to follow. Now, a sense of duty and an ideal of conduct, placed in opposition to impulses and desires in this manner, is something rational and supra-sensory, and demands the activity of an appetency which is also rational and supra-sensory.

Readjustment of the Mode of Life. It happens occasionally, through illness, financial reverses, death in the family, the collapse of a business, etc., that a person is forced to adopt an entirely new plan of life. The readjustment required is both difficult and painful. By shirking this responsibility, one could follow the line of least resistance and avoid much unpleasantness; by changing one's mode of life completely, one must follow the line of greatest resistance and make many sacrifices. Natural inclination prompts persons to adopt the former course. Yet it occurs not infrequently that persons adopt the latter; but in doing so, they are conscious of a great effort, a momentous decision, and a strong determination, in opposition to their inmost natural wishes and inclinations. The existence of volition as a unique mental state, as an

internal act of a distinct mental power, is most evident in experiences of this kind.

Moore is right, when he concludes that no kinesthetic sensations, no feelings of being happy or sad, and no complex of images can account for these facts. The facts demand 'volition' and a 'will.'

The same conclusion must be drawn from the *experiments on volition* made by Ach. In the course of the experiments, his subjects experienced various kinds of sensations, feelings, emotions, images, and intellectual judgments. What distinguished volition from these mental states was the fact that they clearly perceived the *Ego-in-action* in every deliberate decision as the *originator* of the act of willing, and not merely as the subject in which volition occurred. It was precisely this *active interposition of the Ego* in deciding an issue and in making a deliberate choice which manifested the act of the will to them as an experience distinct from all other conscious processes. The experimental work of A. Michotte, Prüm, and of H. M. Wells on the psychology of choosing confirmed the data of Ach. The voluntary action of choice was effected by a definite decision made through an active interposition of the Ego.

Volition, then, is an operation *differing in kind* from other operations and elements of our mental life. As such, it must be the activity of a *specific power*, the will; and the will is in truth, as previously defined, a 'rational appetency.'

Summary of Chapter XV

Besides sense-perception, sensuous appetency, and intellection, man experiences volition, the activity of the will, as a phase of his mental life.

1. *The Concept of the Will.* Man's everyday life manifests many attitudes and acts which reveal the activity of the will. The will is conceived and defined as *rational appetency* or the power to strive for an intellectually perceived good and to shun an intellectually perceived evil.

2. *The Object of the Will.* We strive for material and spiritual things which seem good to us. From the individual things which are good the intellect abstracts the universal concept of the 'good in general.' 'Goodness' is the suitability of a thing to a natural tendency or appetency.

The *adequate object* of the human will is *everything that is good*.

The *formal object* of the human will is the *good as good*, provided it be *suitable to the willing subject*. Whatever is an object of the will, is striven for under the aspect of a 'good.'

3. *Types of the Good.* We distinguish between the ontological, the physical, and the moral good; between the absolute and the relative good; between the objective and the subjective good; between the real and the apparent good; between the disinterested, the delectable, and the useful good. Every good is a 'value,' recognized and appreciated as something perfect or perfective.

4. *Evil and the Will.* Evil is the privation of a required good. By the fact that the will is necessitated by its very nature to strive for the good it is also necessitated to shun evil. When people desire things that are physically harmful or morally evil, they do so because they consider such things to be a 'good' for them.

5. *Motive and Motivation.* A motive is an appreciated value realizable through an act of volition. A *double factor* is involved in a motive: the objective factor of the goodness of the object or experience, and the subjective factor of the intellectual knowledge of this goodness on the part of the willing subject.

Motives may be of a physical, intellectual, or moral character; there are also inner and outer motives.

By *motivation* is meant the arousal of the will from a state of inaction into a state of action. Motives reside in the intellect; the intellect makes the *practical judgment* that this or that thing is desirable and thereby elicits the act of the will.

6. *Natural and Deliberate Volition.* Since the good is the formal object of the will, and since *happiness* is the fulness of good, the will, by its very nature, must strive for happiness; this kind of striving is *natural volition*. Volition is said to be deliberate when, after a consideration of the respective merits of particular values, a preferential choice is made.

7. *Voluntary Control.* By voluntary control we understand the control which the will exercises over the powers and actions of the human organism. Experience proves that we exercise voluntary control, though this

control is neither universal nor uniform. We have *no control* over the functions of the cells. The functions of the vegetative organs and of the external senses are subject to *indirect* control. We have *direct* control in some measure over bodily movements, over the activities of the internal senses, and over the intellect. Voluntary movements have a tendency to become gradually 'mechanized.' Some kinetic units are hereditary; most of them, however, are acquired by direct volition through repetition of acts. Movements may be *actually, virtually or habitually* voluntary. *Determining tendencies* resemble virtual or habitual voluntary actions.

8. *The Existence of Volition.* That volition, as a distinct type of mental experience, actually exists, is proved from the facts of *attention*, from *resolving* on a task, from *reaction-time* experiments, from the *control of emotions*, from the inhibition of impulses and desires, and from *readjustments* of the mode of life.

Experiments on volition reveal the Ego-in-action in every deliberate decision as the *originator* of the act of willing, so that the active interposition of the Ego manifests the act of the will as an experience distinct from all other conscious processes. The act of willing, therefore, demands a *specific power*, the will.

Chapter 16

FREEDOM OF WILL

MAN HAS A WILL — A SPECIFIC POWER WITH A DISTINCTIVE activity. It reacts to the motives presented to it by the intellect. Motives are values which prompt the will to conative action; and usually the will seeks to attain the value which is perceived to possess the greatest amount of realizable good under the prevailing circumstances.

The influence of motives brings up the problem of the *freedom of the will*. It would seem that the predominant motive must always prevail over the will and force it to act. If this were so, freedom of the will could hardly exist. Yet it is the universal conviction of mankind that man has a free will. On what grounds is this conviction based? Is it a rationally justified conviction? Or is it merely an illusion?

The question is of paramount importance, because the entire structure of man's individual and social life rests upon the concept of the freedom of his will. If the human will is free, man is indeed the most privileged creature in the universe; but if it is not free, our entire educational, social, and moral system must be discarded or revised.

Statement of the Problem

The term 'freedom' is used in different meanings. In order to avoid confusion of thought, it is imperative to clarify the concept of freedom as it applies to the will.

In the *widest* sense, freedom is the *absence of external coercion* or restraint which hinders an appetency from expressing itself in external action. A man locked in a room or held by physical force, so that he cannot do as he pleases or is forced to do what he does not want to do, lacks external freedom; when the restraining force is removed, he has 'freedom from coercion.' This type of freedom applies to bodily movements and has nothing to do with the will.

In the *strict* sense, freedom means the *absence of intrinsic necessity or determination in the performance of an act*. Something is 'intrinsically necessary,' when it is determined by its very nature to be what it is and to act as it does. This type of 'freedom' applies to the will when we speak of 'free will,' and we mean that the will is free from intrinsic necessity or determination in at least some of its acts. Hence, when it is said that the will is 'free,' it is implied that the will is not necessitated by its nature to act in a determined manner, but is *capable of choice even when all the conditions for acting are present*.

The advocates of free will do not claim that the will is free in every respect. They admit that it is governed by intrinsic necessity or determination in seeking happiness, as was pointed out in the foregoing chapter. They also admit that the will in many circumstances acts impulsively

and indeliberately. They admit further that certain mental states and conditions make it impossible for the will to exercise its freedom or impair its freedom to such an extent that responsibility is wholly or partially lacking. Such states are sleep, profound absent-mindedness, delirium, pronounced narcosis, hypnosis, marked emotional unbalance, insanity, and in general all disturbances of attention which hinder the intellect from giving proper consideration to a motive. These factors, however, are extrinsic to the will itself.

The *conditions* required for the exercise of free will are: a normal state of attention; an objectively indifferent judgment of the intellect; and a conflict of motives resulting from such an objectively indifferent judgment.

A normal state of *attention* is required. The will can desire only what the intellect proposes to it as good. Obviously, then, anything that interferes with the normal state of attention interferes with the proper judgment of the intellect and thereby with the proper act of the will. An *objectively indifferent judgment* of the intellect is required. In order that a free choice of the will be possible, the intellect must judge that a certain object or act or situation is good under one aspect but evil under another; if the object or act or situation were judged to be altogether good and therefore essential for happiness, the will would of necessity strive for it, and freedom of choice would be impossible. Given this objectively indifferent judgment, a *conflict of motives* arises, and that is a condition which is also required for the exercise of free will. The will cannot desire an evil as such; it can desire only a good. In order,

then, that the will be able to exercise its freedom, it must choose between two or more goods which act as motives; in other words, there must be a conflict of motives, before there can be a choice between them. The freedom of the will consists precisely in this that it has the power of self-determination in arbitrarily choosing between conflicting motives. The intellectual judgment which presents an object or act or situation to the will as 'objectively indifferent,' that is to say, as being something which is neither altogether good nor altogether evil, is termed the *root of freedom*. Since the will itself is 'subjectively indifferent' toward the presented motives, the freedom of the will is sometimes termed the *freedom of indifference*. And since this subjective indifference enables the will to make an arbitrary choice between motives, the freedom of the will is also designated the *freedom of choice*.

The will exercises its free choice in three distinct ways, and correspondingly we distinguish between *three types of freedom* in the acts of the will.

First, there is the *freedom of exercise or contradiction*. The will can choose freely between willing and not willing, between acting and not acting. Since it is a question here of the will exercising or not exercising its power of choice, it is called 'freedom of exercise'; and since exercising and not exercising are contradictory opposites, it is also called 'freedom of contradiction.' A person, for example, can freely choose between studying and not studying, between eating a piece of candy or not eating a piece of candy.

Second, there is the *freedom of specification*. From this point of view, the will can choose freely between one object

and another object and therefore also between one act of the will and another act of the will; it specifies which kind of object or act shall be the goal of its choice. A person, for example, decides freely whether he shall study or take a stroll, whether he shall eat a piece of chocolate or a caramel.

Third, there is the *freedom of contrariety*. The will possesses the freedom of choosing freely between a moral good and a moral evil. Good and evil are contrary opposites. A person, for example, can choose freely between telling the truth and telling a lie, between acting chastely and acting impurely. The freedom of contrariety can be reduced to one of the first two, since it is a choice either between acting or not acting or between one object and another object.

From the above it should be clear that the freedom of the will does *not consist in motiveless* volition. The will cannot act without a motive of some kind, because it can desire an object or an experience only in so far as it is intellectually apprehended as 'good.' Nor does it consist in *causeless* volition. The self or person possessing the will is the cause of the free act of the will. The will is not a thing apart, existing and acting independent of the person or self who is the abiding subject of the will. The motive is the moral cause, and the person or self is the efficient cause. It is permissible to say that the will is the cause of its own act, provided it be understood that the will and its act must ultimately be referred to the person or self as the agent operating through the will.

Free will is *defined as the ability of the will, all conditions for action being present, to decide whether to act or not to act and whether to act in this manner or in that manner.* From a psychological standpoint, free will is the ability to choose arbitrarily between conflicting motives through the active interposition of the Ego. Many authors define it briefly as 'the power of self-determination.'

The *essence* of the freedom of the will, as just defined, consists in indetermination, so that the will, no matter what the strength of the conflicting motives or the nature of the antecedent external and internal conditions for action may be, is *not determined to act by necessity*. This doctrine is therefore designated as *indeterminism or libertarianism*. This indeterminism, however, is not absolute, because in the pursuit of 'happiness' the will is, as stated before, determined. We advocate, then, a relative or moderate *indeterminism*.

Determinism

The doctrine opposed to free will is styled *determinism or necessitarianism*. Modern psychology has adopted the former term. According to this doctrine, the will is not intrinsically free, but is determined by the antecedent psychical and physical conditions and causes to act as it does; it is necessitated in its volition. Determinism appears in a variety of forms.

Among the ancients, many held the view that the entire course of man's life is predetermined by an inexorable *fate* or *destiny*. Astrology is akin to this. Some Christian sects

denied the existence of free will; the activity of creatures is only apparent, because *God alone* is active. In modern times, we find free will denied by *materialists and pantheists*. The materialists admit the existence of nothing but matter and material activities. Since matter is governed completely by the necessary laws controlling chemical, physical, and mechanical agencies, there is no place for a free-acting cause like free will. The will is determined in its volition by physical factors, such as the hereditary constitution of man and the environment in which he lives, and by psychical factors, such as images, feelings, emotions, and the preponderance of motives. If 'psychical' factors are mentioned, they are usually considered to be mere refinements and complexes of material factors. The pantheists maintain that all reality is ultimately one, God or the Absolute. The world, man included, is but a phase in the eternal evolution of the Absolute, and this evolution takes place according to laws which operate with inevitable necessity. There is no freedom of action anywhere. Among the materialistic theories denying free will we must place the philosophical systems of associationism, positivism, and behaviorism; the systems of Spinoza, Fichte, Schelling, Hegel, and their offshoots are representative of pantheism in one form or other. All are deterministic.

Some modern philosophers and psychologists speak of the will as if they admitted its freedom of action. Analysis of their ideas and explanations, however, reveals that they interpret 'free will' in a fashion which is either a perversion of the true concept of freedom or which makes the will so dependent on the conditioning factors as to preclude

genuine indeterminacy. It is a case of what William James has described as "soft determinism."

Relative Indeterminism

What, then, is the *true problem* of free will?

It is this: All the conditions and circumstances required for volition being given, is the will, when confronted by *conflicting motives* presented by the intellect in a normal state of attention and deliberation, *compelled and determined to decide for one of the motives* to the exclusion of the others? Or, on the contrary, everything given as just stated, is it within the ability of the will, through the *active interposition of the Ego*, to make an *arbitrary choice* between these conflicting motives, *irrespective of their relative attraction*, by simply *determining itself to choose* any one of the motives and thereby conferring a *subjective preference* on this one over the others? If the former alternative is verified, there is no freedom of the will; if the latter, then the will is truly free in at least some of its acts.

We claim that the will is truly free, as specified, in some of its acts; that is all that is needed to disprove the universal determinism advocated by the determinists. The proofs for the truth of the freedom of the will are of three kinds: psychological, based on the evidence of our conscious experience; ethical, based on the concepts of right and wrong; and metaphysical, based on the philosophical concept of the will as a rational appetency. These proofs will now be treated individually.

PSYCHOLOGICAL PROOF

As a preliminary observation, it must be stressed that the court of last appeal in matters of knowledge is consciousness; the testimony of our consciousness is the ultimate criterion of natural truth for man. If this criterion is rejected by a philosopher or psychologist, all knowledge must end in universal skepticism.¹ Our consciousness gives indubitable testimony to the fact that our *will is free in many of its acts*.

By means of an *introspective analysis* of the *will in action*, I am conscious that the will is not only capable of arbitrary choice between motives, but actually makes such an arbitrary choice. True, motives are present, and these motives attract the will to action; at the same time, however, I am conscious that these motives do not force the will to action, but leave it *within the power* of the will, notwithstanding the attractiveness of the motives, to act or not to act, to act this way or that way. The will settles the issue through an active interposition of the Ego, by deciding simply *as it pleases*.

Everyday experience proves this contention conclusively. The idea presents itself to me to take a stroll; but I am also inclined to continue with the reading of this interesting book. Both are pleasant to me. What shall I do? I realize that it is entirely up to me 'to make up my mind.' Neither motive is compelling. I decide to take a stroll. Shall I go to the left or to the right? I have no particular preference; there is certainly no necessity to go in one direction rather than in the other. But which shall it be? Let it be to the right; "it makes no difference anyhow." And to the right I

stroll. During this entire procedure I am conscious that in the final analysis everything I do depends upon my *free decision*; my will is not determined, except in so far as it *determines itself* to act.

The fact of free decision is brought out very clearly in so-called *indifferent acts*. I lift my hand, for instance, about six inches above the table, palm upward. I can now deflect it one inch (or shall it be two inches? or three?) to the right or the left; I can also leave it as it is. I can crook my index finger (or shall it be the little finger? or the thumb?); I can also leave the hand as it is. What motive have I for doing any of these things? There is no motive in the actions themselves which prompts or necessitates me. The only motive I can discover is this: I merely *want* to; it is *my will* to do so; I can *do as I like*. The will acts simply because it *decides* to act rather than not act in the described manner, and there is nothing that compels it. The particular actions, taken for themselves, are indifferent; the decision lies completely and freely in the power of the will. Many actions are performed in this way.

In particular, a number of mental processes reveal the free will in action.

Attention. Attention, besides manifesting the existence of volition as a distinctive mental operation, also manifests the 'freedom' of the will. Attention is often *selective* and *preferential*, due to a free decision on our part. In working out a problem, in preparing an address, in pursuing a discussion on some topic, etc., we are conscious of the fact that we *ourselves* direct the marshaling of our ideas, force some of them to dwell in our consciousness longer than

others, divert the entire train of ideas into other channels, recall them for further consideration, dismiss them at our pleasure, and so forth. We can restrict our attention exclusively to motives of less agreeableness, if we so desire, and give these the preponderance. In fact, it lies in our power of the will to be or not to be attentive, and just how long and how intensively to be attentive. In all phases of voluntary attention we are conscious that we are the *free cause* of the operation.

Deliberation. It is a fact of experience that we often deliberate on the merits of conflicting motives, ask counsel from others as to what course we should pursue, and so on. We are conscious that it lies in our power to deliberate or not to deliberate. If we decide to deliberate at all, it is in our power to carry on the deliberation for hours or days or months or only for minutes. We can interrupt and resume our deliberations as we please. No matter what the motives and their strength may be at the moment, we can withhold our decision and look for counter-motives. All the while we are conscious that this process of deliberation is freely inaugurated, freely continued, and freely terminated by the active interposition of the Ego; and this process is perceived to be totally different from the familiar impulsive character of many actions which occur in our life more or less against our will. Motives are present, certainly, but our consciousness is witness to the fact that they do not compel our consent.

Decision in Matters of Conduct. In the course of a temptation, we are irresistibly convinced that consent lies in our free power, to give or to withhold. We are very much

attracted by the allurements of the temptation; to consent means to follow the line of least resistance, while to resist means to follow the line of greatest resistance. We resist, though the effort is very painful, and we know that thereby we are struggling against the preponderant motive, the motive of greatest attraction. It amounts to what William James has called "deliberately thrusting a thorn in one's flesh." The main point here, too, is the consciousness that it would be easy to yield and that the yielding would be a free decision of our will, just as resisting is a difficult matter and is the laborious result of a hard-fought volitional battle freely undertaken. No quibbling can shake our conviction that in such circumstances our will is truly free.

Laboratory experiments confirm the evidence of everyday experience.

A. Michotte and H. M. Wells devised a number of experiments to test the *act of choice*. There is no need to describe the details of the procedure. In Michotte's experiments the subjects had to choose between the addition or subtraction, the division or multiplication, of numbers presented to them. In Wells's experiments the subjects were asked to choose between known liquids and to drink them; the choice was between liquids which were equally pleasant, equally unpleasant, or equally indifferent as to taste. There was nothing difficult about any of the tests. The motives of attractiveness or unattractiveness were, so far as the subjects were aware, balanced so evenly that they experienced no preponderance of motive which induced them to choose one alternative in preference to the other. Here was, to all appearances, the predicament of

Buridan's ass that starved to death — so the story claims — between two equally attractive bundles of hay. Prior to the act of choice itself, there was *neither an objective nor a subjective difference between the alternatives* for the subjects. Yet they made their choice. The subjects were aware of the fact that they *simply decided on one alternative* by an act of self-determination, thereby giving added strength to one motive, although both motives were of equal objective strength and value. It was not the motive which determined the choice; it was the choice of the *Ego-in-action* that determined which of the equal motives shall prevail. By concentration on one course of action, to the exclusion of the other, the *Ego itself* (concretely, the person' or 'will') cut short all deliberation and *decided to act*, without regard to the objective equality of the motive, in favor of one of the alternatives. Deciding to act is but another way of saying that the human will is *free in its choice*, when confronted by conflicting motives. Scientific psychology thus also confirms the freedom of the will.

ETHICAL PROOF

Nothing, perhaps, makes us more convinced of the freedom of our will than our *experiences about right and wrong*.

We experience *joy* and *satisfaction* in many of our actions, because we are conscious that we have done something 'morally good' and have 'performed a duty.' On the other hand we experience remorse and *repentance*, because we have done something 'morally wrong' and have

‘neglected our duty.’ We feel in ourselves the presence of a sense of *obligation* and of *responsibility*. We know that we ought to do something and that it is within the power of our will to do it or not to do it. If we do it, we have the experience of joy and satisfaction; if we do not do it, we have the experience of remorse and repentance. We know, beyond cavil and dispute, that we are *bound by the law* in our conduct; but we also know that we are *not forced* by this moral law. We can, but we need not, obey the moral law.

Conduct of such a sort, however, involves free will. Without the existence of the freedom of choice in such matters, such an attitude toward our own conduct would be both ridiculous and irrational. If the acts of our will are as necessarily determined as the falling of a stone or as the course of an electric current, then there should be *no experience of a difference between right and wrong acts*; all acts are *equally necessary*. We have, however, the definite experience of blameworthiness and praiseworthiness with reference to many of our acts, and we make a clear-cut distinction in this regard.

If we unknowingly and unintentionally injure someone in his person or property, we naturally deplore the fact and express our regret; but we do not feel guilty of any wrong, because we did not will the harm done. If we break a leg in an unavoidable accident, we are sorry; but we do not really reproach ourselves. But if, contrary to our better judgment, we are reckless, fall, and thereby suffer a serious hurt, we feel remorse for our rash action, clearly perceiving that we *ought* not to have done it and *could* have avoided it. Such an attitude, however, has sense only under the supposition

that our will is free in its decisions and not intrinsically determined in its acts.

The *universal conviction of mankind* is in accord with our personal experience in this respect.

All nations and individuals speak of their freedom, of their immunity from necessity. All languages express ideas of right and wrong, virtue and vice, command and permission, merit and demerit, natural defects and culpable delinquencies, praise and blame, reward and punishment, appeal and threat, etc. All men thereby give expression to the conviction that we possess freedom of the will.

Before action, men deliberate, seek and give counsel, exhort and induce others to follow a certain course of action by promises of reward or threats of retribution. All nations have *courts* which punish the criminal for his misdeeds and a police force which protects the law-abiding citizen and curbs the nefarious activities of the lawbreaker. All nations have *laws* governing traffic, business transactions, and public morals. All nations enter into *treaties* with one another, regulating rights and duties, so as to safeguard international peace and promote the welfare of peoples.

Such actions and laws would be foolish and useless, if man has no free will and cannot help acting as he does. This universal conviction of mankind cannot be explained except by the fact that the evidence for free will is inescapable and irrefutable.

The *practical life of the determinist* is also proof for the freedom of the will.

Like idealism, determinism is an unlivable and *unlivable doctrine*. In their dealings with other people and in their

personal conduct, determinists behave, not on the supposition that man in all his decisions and actions is controlled by an inexorable determinism, but in a manner which is patterned on the conviction that man is indeed the lord and master of his conduct. The structure of society is based on the principle of free will and responsibility, and the determinists not only expect others to live according to this principle but do so themselves. They make a contract and carry out its stipulations, and they demand that the other party do the same; they also seek redress before the courts for violations of the contract. They respect the person and property of other citizens, and demand the same consideration for themselves. They believe in the 'rights' and 'duties' of their citizenship, although rights and duties can have no legitimate meaning in a deterministic doctrine. They observe the regulations and laws of their community and country like the ordinary man of the street. They praise and blame people for their actions, forgetting their doctrine of determinism for the time being. Determinists are determinists on *theoretical* grounds; in actual life they are libertarians like the rest of men.

Since all men, including the determinists themselves, behave according to the principle of free will, what could possibly be assigned as the *cause* for this *universal conviction* and *behavior*? Not passion, because freedom, involving ideas of responsibility and punishment, is opposed to passion in this case. Not ignorance, because all humanity cannot remain ignorant for long in a matter of such vital moment. The cause can only be *rational insight*, and this must be based on *truth*, because human nature cannot lead

man into an irresistible error in something which affects his essential well-being and happiness.

METAPHYSICAL PROOF

We have a further proof of the freedom of the will in the very *nature of the will itself*.

The will is a *rational appetency*. Its proper and connatural object is the *good as such*; to this it cannot be indifferent. Since happiness is the fullness of good, the will must desire it and strive for it; in this regard it is not free. Similarly, whatever is perceived by the intellect as a good in every respect, as an essential means to happiness, irresistibly draws the will in its direction.

The reverse is also true. The will cannot desire the evil, provided it is apprehended by the intellect as an evil and proposed as such to the will. Whatever is perceived to be an *evil in every respect*, must be rejected by the will; here, too, the will is not free. The will, by its very nature as a rational appetency, must strive for the good as such.

So far, then, as the intellect perceives *something good* in an object, it is *desirable*; and the will can desire it and strive for it. So far as the intellect perceives *something disagreeable* in an object, it is *undesirable*; and the will can turn away from it and reject it. Now, there is no creatural object which is an absolute good in every respect; all objects have limitations and deficiencies of some sort which make them more or less undesirable. In as much as every object contains some good, the will can desire it; and in as much as it contains some deficiency, the will can reject it.

Since a creatural object is neither absolutely good nor absolutely evil, the will can desire or reject it, depending upon whether attention is centered on it as a good or as an evil. All creatural objects, whether material or spiritual, being partially good and partially not good, the will can strive for them under the aspect of their desirability or reject them under the aspect of their undesirability; the will is not constrained in either direction. In fact, because of this dual aspect of all creatural things, the will is not compelled to act at all. Even the *act of volition itself* can be apprehended by the intellect as something partially good and partially not good, so that it lies within the power of the will to exercise volition or not to exercise it.

The only object to which the will is irresistibly drawn is the absolute good. Concretely, this is the *Infinite Good*, namely, God Himself. However, the will can desire only what the intellect perceives and proposes. If our intellect, while we sojourn here on earth, could perceive God as He really is in all His infinite perfection and goodness, we would be conscious that He constitutes our ultimate and essential happiness in an infinite measure. Unfortunately, we have no adequate concept of God. As Maher rightly observes: "The inadequate and obscure notion of God possessed in this life, the difficulty of duty, the conflict of man's pride and sensuality with virtue, all make the pursuit of our true good disagreeable in many respects to human nature, so that we can only too easily and freely abandon it."² It thus happens that the will is able to love God or not to love Him, to seek Him or not to seek Him, to desire Him or to reject Him.

Hence, the *freedom of the will is the result of man's rational nature*, which enables him to have the notion of a universal good that is desirable in every respect and also the notion of *particular goods* that are partly desirable and partly undesirable. Because of this dual character of particular goods he can decide to exercise or not exercise his power of choice with regard to them, and that is *freedom of exercise*; he can prefer one particular good to another particular good, and that is *freedom of specification*; he can choose between the morally right and the morally wrong, and that is *freedom of contrariety*.

OBJECTIONS AGAINST FREEDOM OF WILL

Our modern era has become so impressed with the progress made by the physical sciences that it is hardly capable of interpreting anything except in physical and mechanical concepts. The spiritual and immaterial is alien to the minds of many modern philosophers and psychologists. In consequence of their materialistic, mechanistic training, the freedom of the will is something 'unintelligible' and 'inconceivable.' Causes, as they come to know them in physical nature, act necessarily, and so it happens that the concept of 'cause' is synonymous in their reasoning with 'necessarily acting cause.' The will as a 'freely acting cause' is to them a contradiction in terms: they see no place for it in a mechanically operating universe.

The *facts* in favor of the freedom of the will are very clear, so far as everyday experience goes; they cannot very

well be denied by these determinists. Yet the freedom of the will is diametrically opposed to the *theoretical assumptions* of their materialistic, mechanical system of philosophy. Loath to admit the error of these assumptions and of their philosophic convictions, they have advanced many objections against the freedom of the will. The point of the attack varies considerably. Some objections are psychological in nature, some are metaphysical, and some are based on the physical, physiological, and sociological sciences.

While many of the arguments against free will are specious and amount to nothing more than sheer quibbling, some of them deserve serious consideration. The more important objections will now be stated and answered.

Unconsciousness of Freedom

J. Stuart Mill (1806—1873) voices an objection against the freedom of the will on psychological grounds. He contends that we *cannot be conscious* of this freedom. To be conscious that we are free in our volition, it would be required, before we act, that we be conscious of the fact that we could really act otherwise than we do. Consciousness, however, Mill claims, merely tells us what we actually do or feel; it never tells us what we are *capable of doing*. In other words, we are conscious of the act of willing, but not of the power of willing; hence, it is impossible to know whether the power is free or determined.

We admit that the power of the will as such is not an object of direct consciousness. Mill, however, failed to note that every act of volition involves the actuation of the power of the will, the *fieri* or *developmental process* of the volitional act itself.

In the developmental process of many volitional acts, I am conscious that they are *elicited* by motives, but the motives *do not determine* and necessitate the acts; *I myself* determine the acts. I clearly perceive that I have here a motive plus something else which makes the impulse of the motive effective; the act of the will is thus eventually determined, not by the motive, but by the will itself. An analysis of the act of volition shows that two factors are required: an impulse flowing from a motive which elicits, but does not compel, me to act; and a *positive consent of my will*, supplementing the deficiency of the objective motive. At times, therefore, I observe that I consent to the impulse originating from the motive, and at other times I observe that I withhold my consent to the impulse originating from the motive; whether the act of volition is set or not set, thus depends on the *active interposition of my Ego* and not merely on the presentation of the motive. So long as the process and *fieri* of volition is protracted and not completed, the final decision to act or not to act, to act this way or that way, rests in my power of determination. The will, therefore, is the master of its own determinations; and as such it is free, because the *consent*, as I know from my internal experience, is a freely exercised act of the will. The experiments of Ach and others, mentioned in the

preceding chapter, have definitely revealed the Ego-in-Action in every deliberate decision.

ILLUSION

Determinists frequently assert that our conviction of the freedom of the will is but an illusion based upon an *ignorance of the causes* which produce the acts of the will. Since we are not conscious of the underlying causes which determine the will to act, we have the *feeling* of freedom in our acts; in reality, however, all acts of the will are determined.

In answer to this objection, we assert, first of all, that an appeal to ignorance is the worst sort of argument anyone can advance. Determinists labor under this ignorance as well as the libertarians. The determinists have no more right to suppose that the unknown causes of our voluntary acts are necessary in their operation than that they are free; we simply could not know whether the will is free or determined under any circumstances.

Secondly, this assertion of the determinists *contradicts the experience of consciousness*, and consciousness is the ultimate source of knowledge in this matter. Our experience tells us that the ignorance of the cause of actions occurring within us does not necessarily induce in us the conviction that this cause is free. On the contrary, when we act on a momentary impulse and without reflection, not knowing why we act, then we are convinced that our act was *involuntary, unfree, and irresponsible*. On the other hand, when we reflect upon a project with careful deliberation,

consider all its advantages and disadvantages, investigate the various means at our disposal, lay out a plan in all its details, weigh all the motives for and against a course of action — in a word, when our knowledge is at its best — then it is that the conviction of the *freedom* of the will and of its choice is greatest. It is, therefore, the incontrovertible testimony of our consciousness that our conviction of freedom is not based on the illusion of ignorance but on the certainty of knowledge.

It is true, of course, that *subconscious motives* often influence the will. A *mental act* or attitude frequently brings about the performance of an external act contrary to our resolutions. If we bear in mind, however, the conditions required for the free exercise of the will, as stated in the first section of this chapter, it will readily be observed that one or the other of these conditions has not been verified. No libertarian claims that *all* acts of the will under *all* circumstances are free, but borderline cases do not invalidate the instances where the requisite conditions are clearly perceived by consciousness to have been verified for the free exercise of the will. While many cases will always remain doubtful, many cases of the free exercise of the will must be allowed by an unbiased observer.

It is the verdict of our consciousness that the will is free in many of its acts. This verdict must be accepted as true; otherwise the truth-value of our consciousness is destroyed, and skepticism is the inevitable result.

THE STRONGEST MOTIVE

It is a stock argument of determinists that the *strongest motive* always does and always must prevail, so that the will is intrinsically determined to yield to the strongest motive; the will, therefore, is not free in its choice.

The objection is invalid. Since the will is an appetency and as such can strive only for what is perceived to be good, it is obvious that the motives draw the will in proportion to the amount of value they contain. Slight values influence the will slightly, great values influence it greatly. It is but natural, therefore, that the will, under ordinary and normal circumstances, should and does strive for the greatest value contained in the proposed motives. It would indeed be most unusual, if this were not the case.

The argument of the opponents, however, to be valid, must prove that man, *under all conditions*, is necessitated to choose what is intellectually apprehended as possessing the *greatest objective attractiveness* for the will.

It will not do to assert, as the British philosopher Bain apparently asserts, that the strongest motive is the one which actually prevails. He is guilty of a begging of the question. Certainly, the motive which is willed is the one which prevails, and in a sense this motive is the strongest. This only means that the motive which prevails actually prevails, but does not settle the question whether the will is *determined or free* in making a particular motive prevail.
